is produced by the direct action of carbon dioxide on ammonia in cooled absolute alcohol. It is a white crystalline powder. The *sodium* $\text{NaCH}_2\text{NO}_2\cdot\text{H}_2\text{O}$ and *potassium* KCH_2NO_2 salts are also crystalline; the *calcium* salt

is insoluble in alcohol and crystallises from concentrated ammonia solution in four-sided prisms.

Carbamyl chloride (chloroformamide)

prepared by passing hydrogen chloride over heated metallic cyanates, or carbonyl chloride over heated ammonium chloride, forms long, broad needles, m.p. 50°, b.p. 61°–62° (Gattermann and Schmidt, Ber. 1887, 20, 858).

Urethane, *ethyl carbamate* $\text{NH}_2\cdot\text{COOEt}$, prepared by the action of ammonia on ethyl carbonate or ethyl chlorocarbonate; by heating urea nitrate with alcohol; or by the action of alcohol on carbamyl chloride, crystallises in large pliable plates or prisms that break with a fibrous fracture, sublime readily, melt at 50° and boil at 184°. The system urethane-benzene forms a eutectic containing 97 mols. p.c. at 4.2°, and solid solutions in the interval from 97 to 100 mols. p.c. of benzene (Puschin and Masarvitch, J. Russ. Phys. Chem. Soc. 1914, 46, 1366). For the use of urethane as a cryoscopic solvent, see Bruni (Atti R. Accad. Lincei, 1918, [v.] 27, i. 321). When heated with water or ammonia, urethane yields a small quantity of urea; for the explanation of this reaction, see Werner (Chem. Soc. Trans. 1918, 113, 622).

Urethane has therapeutic properties, being employed as a hypnotic. Certain of its substituted derivatives have similar properties; for example, *phenylurethane* or *euphorine*

methylpropylcarbinal urethane or *ledonal*

and *octarine-urethane*, m.p. 110° (Knoll & Co., D. R. P. 232785).

Urethanes when heated with calcium or strontium bromide yield double compounds of the urethane and the metallic bromide;

is a powerful hypnotic (v. J. Soc. Chem. Ind. 1915, 34, 1166; and Gebe & Co., D. R. P. 284734).

p-Benzylphenyl carbamate, m.p. 144°, *p*-isomylphenyl carbamate, m.p. 73°–74°, *p*-butylphenyl carbamate, m.p. 123°–124°, *p*-isopropylphenyl carbamate, m.p. 93°–95°, *p*-butylphenyl *N*-dimethylcarbamate, m.p. 92°; *o*-allylphenyl carbamate, m.p. 122°–123°, are white powders, sparingly soluble in water, and possess anthelmintic properties (Syntetic Patents Co., U.S. Pat. 1252452, and Farbenfabriken vorm. Friedr. Bayer & Co., D. R. P. 296889, from Chem. Zentr. 1917, i. 714).

4-Hydroxy-3-urethano-phenylarsine

is a white powder, (Farbwerke vorm. Meister, Lucius and Brüning, D. R. P. 275216, addition to D. R. P. 268220).

Nitrourethane $\text{NO}_2 \cdot \text{NH} \cdot \text{COOEt}$ melts at 64°, is readily soluble in water and alcohol and forms metallic salts, the *potassium*, *mercury*, and *silver* salts having been prepared (Thiele and Lachmann, *Annalen*, 1895, 288, 304). From spectrochemical considerations Brühl assigns the formula

physikal. Chem. 1898, 26, 47; 25, 577). *Nitroso-urethane* $\text{NO} \cdot \text{NH} \cdot \text{COOEt}$ melts and decomposes at 51°–52° and does not develop a purple colour with ferrous sulphate and potassium hydroxide: the *silver*, *potassium* and *ammonium* derivatives are yellow (Thiele and Lachmann, *l.c.*). From index of refraction values, Brühl regards nitro-

sourethane as diazourethane $\text{N} \begin{array}{c} \diagup \text{O} \diagdown \\ \diagdown \text{O} \diagup \end{array} \text{NH} \cdot \text{COOEt}$

(Ber. 1902, 35, 1148), whilst Hantzsch formulates it as an *antidiazohydrate* $\text{HO} \cdot \text{N} \cdot \text{N} \cdot \text{COOEt}$ (*ibid.* 1899, 32, 575). *Dibromourethane* $\text{NBr}_2 \cdot \text{COOEt}$ has b.p. 100°–104°/10–11 mm. (Diels and Ochs, Ber. 1907, 40, 4571). *Ethylchlorocarbamate* $\text{NHCl} \cdot \text{CO}_2\text{Et}$ is obtained by the action of chlorine on ethyl carbamate if the solution is kept well cooled; it is a pale yellow viscous oil, b.p. near 99° (decomp.) (Datta and Gupta, J. Amer. Chem. Soc. 1914, 36, 386); it is slowly hydrolysed by water, yielding ethyl 4-chloromethylcyclohexylmethylenhydrazineimide 1:3-dicarboxylate $\text{CH}_2\text{Cl} \cdot \text{CH} \begin{array}{c} \diagup \text{N}(\text{CO}_2\text{Et}) \diagdown \\ \diagdown \text{N}(\text{CO}_2\text{Et}) \diagup \end{array} \text{NH}$, colourless needles, m.p. 143°, which forms a crystalline *acetyl* derivative, m.p. 117°–118°, and *imide chloride*, m.p. 75°–76° (Datta and Chatterjee, *ibid.* 1922, 44, 1538).

Urethane forms condensation products with aldehydes and keto acids. *Chloralurethane* $\text{ClCH}(\text{OH})\text{NH} \cdot \text{COOEt}$ has m.p. 103°; *bromalurethane* $\text{CBr}_2\text{CH}(\text{OH})\text{NH} \cdot \text{COOEt}$ has m.p. 132° (Birchoff, Ber. 1874, 7, 628, 1078; Conrad and Hook, *ibid.* 1903, 36, 2206; Simon, *Compt. rend.* 1901, 133, 535; Simon and Chavanne, *ibid.* 1906, 143, 51).

Thiourethane, a mixture of the isomeric thiourethanes, is obtained by acting on an alcoholic solution of potassium thiocyanate with concentrated hydrochloric acid; these correspond with two of the isomeric forms of the hypothetical thiocarbamic acid, *ethyl xanthamide* $\text{NH}_2 \cdot \text{CS} \cdot \text{OEt}$, m.p. 38°, and *carbonylthioethylamine* $\text{NH}_2 \cdot \text{CO} \cdot \text{SEt}$ (Blankenhorn, J. pr. Chem. 1877, [ii.] 16, 358).

M. A. W.

URGINEA. v. SQUILL.

URIC ACID, 2:6:8-trioxypurine

was discovered in human urine by Scheele in 1776 (*Opuscula*, 1776, 2, 73), independently by Bergmann in urinary calculi (*ibid.* 1776, 4, 232), and in 'chalk-stones' by Pearson in 1798 (*Trans. Roy. Soc.* 1798, 15).

Uric acid occurs in the urine of all animals, though only to a small extent in the case of herbivorous animals; the average daily excretion in normal man being 0.597 grm. (Hanzlik and Hawk, J. Biol. Chem. 1908, 5, 355). It occurs in the excrement of birds, reptiles, scaly amphibians, snails and insects; the wing scales of the group of butterflies known as the white *Pieridae* contain uric acid, those of the yellow *Pieridae* contain, as their pigment, a yellow derivative of uric acid, which can be obtained synthetically by heating uric acid with water in sealed tubes at a high temperature (Hopkins, *Proc. Roy. Soc.* 1894, 57, 5). Uric acid is a normal constituent of the organs and blood of birds, but only occurs in human blood under certain pathological conditions. For its occurrence in blood, v. Bass (*Amer. Chem. Abs.* 1914, 1602).

Preparation.—Uric acid can be isolated from serpent's excrement, bird's excrement or guano by boiling the material with dilute alkali hydroxide or milk of lime, filtering the hot liquid and precipitating the uric acid by adding excess of hydrochloric acid to the filtrate. Uric acid can also be obtained from the yellow acid urates deposited from urine; this is boiled with sodium hydroxide until it ceases to evolve ammonia, the liquid is filtered and the acid sodium urate precipitated from the filtrate by means of carbon dioxide; this is redissolved in sodium hydroxide and the solution decomposed by acetic acid, or the hot solution of the alkali salt may be purified by boiling with a little potassium permanganate or dichromate and the filtrate decomposed by hydrochloric acid.

Synthesis.—Uric acid was first synthesised by Horbaczewski by carefully fusing glycine with 10 to 15 times its weight of urea in small quantities at a time, until a considerable quantity of precipitate had formed in the molten mass; the uric acid was precipitated in the form of its sparingly soluble silver magnesium salt, which on treatment firstly with potassium sulphide and subsequently with hydrochloric acid, yielded pure uric acid (Monatsh. 1882, 3, 796; 1885, 6, 386). Compare, however, Behrend (*Annalen*, 1925, 441, 2159; *Chem. Soc. Abstr.* 1925, i. 441). Further syntheses were effected by Horbaczewski

(*ibid.* 1887, 8, 201) by fusing trichlorolactamide with 10 parts of urea

and by fusing trichlorolactic acid with urea (*ibid.* 1887, 8, 584).

In 1863, Baeyer (Annalen, 1863, 127, 3, 234) synthesised *pseudouric acid*, starting with malonic acid and urea; but it was not until 1895 that Fischer and Ach (Ber. 1895, 28, 2473) showed that uric acid could be readily obtained from pseudouric acid by fusion with oxalic acid, or by boiling with hot dilute mineral acids (Fischer, *ibid.* 1897, 30, 559); a complete synthesis of uric acid from malonic acid and urea is therefore represented by the following equations:

Traube's synthesis of uric acid, starting with cyanacetic acid and urea, is also important, and by substituting alkyl ureas for urea, the method can be extended to the preparation of substituted uric acids. Cyanacetylurea, prepared by the condensation of urea with cyanacetic acid, is converted by the action of alkali into 4-amino-

2:6-dioxypyrimidine, from which 4:5-diamino-2:6-dioxypyrimidine is obtained by reducing its isonitroso derivative; this diamine condenses with ethyl chloroformate to form a urethane derivative, from the sodium derivative of which uric acid is produced by heating at 180°-190° (Ber. 1900, 33, 1375, 3035).

Properties. Pure uric acid forms a colourless microcrystalline powder consisting of rhombic transparent plates or prisms; as precipitated from urine or guano extracts, the crystals are yellowish red or brown. These exhibit, under the microscope, characteristic irregularities in form, due to the rounding of the obtuse angles of the rhombic prisms, and the interpenetration of the crystals, and present the form of dumb-bells, whetstones, rosettes of

prismatic crystals, six-sided irregular plates or rectangular plates with partly jagged sides.

Uric acid is odourless and tasteless; it is sparingly soluble in water, one part dissolving in 39,480 parts at 18° (His and Paul, Zeitsch. physiol. Chem. 1900, 31, 41), or 15,505 parts at 37° (Gudzent, *ibid.* 1909, 60, 27). When shaken with water, uric acid decomposes so that the solubility tends to increase with the time; the increase is only noticeable at the end of 24 hours

This is the most important synthetic method of preparing uric acid, and by replacing urea by its alkyl or aryl substituted derivatives, it is possible to prepare the corresponding alkyl or aryl substituted uric acids.

The synthesis of uric acid effected by Behrend and Roosen (Annalen, 1888, 251, 235), starting with ethyl acetoacetate and urea, is represented in the following series of equations:

and then rises rapidly until at the end of 10 days the solubility is 11 times as great as at the end of a few hours, and in the same time the electrical conductivity has increased 55 times (Gudzent, *l.c.*; cf. Biltz and Herrmann, *Annalen*, 1923, 104). The supersaturation which occurs when a warm aqueous solution of uric acid is allowed to cool to a room temperature in contact with solid uric acid is probably the cause of the high values for the solubility found by Bensch (*Annalen*, 1845, 54, 190); Behrend and Roosen (*Annalen*, 1889, 251, 250). The molecular electrical conductivity of a saturated solution of uric acid is 32.24 at 18° (His and Paul, *l.c.*) or 33.92 at 37° (Gudzent, *l.c.*); the dissociation constant $k=0.000151$ at 18° or 0.000233 at 37°. See also Kanitz (Zeitsch. physiol. Chem. 1921, 116, 96). Uric acid has the power of adsorbing precipitated colloids from their solutions. If a trace of dye is added to a hot saturated solution of uric acid, coloured crystals of the latter are deposited from the cold solution (Benoit, *Compt. rend. soc. biol.* 1919, 82, 1051, 1052). Uric acid is fairly readily soluble in lactic acid, acetic acid (see Rossi, *Biochem. Zeitsch.* 1913, 54, 297) or warm concentrated sulphuric acid. For the influence of hydrogen-ion concentration on its solubility, see Jung (Helv. Chim. Acta, 1922, 5, 688). It dissolves in glycerol, but is insoluble in alcohol or ether; it dissolves readily in aqueous solutions of alkali hydroxides, of lithium carbonate, and of certain bases such as ethylamine, propylamine, piperazine, but is only sparingly soluble in solutions of urotropine (hexamethylenetetramine), *lycetol* (piperazine tartrate) or ammonia (Stevens and May, *J. Amer. Chem. Soc.* 1911, 33, 434; v. also Hanzlik, *Amer. Chem. Abs.* 1916, 1226). The solubility of uric acid in a 1 p.c. solution of sodium salicylate is twice as great, and in a 0.1 p.c. solution of sodium 2-phenylquinoline 4-carboxylate three times as great as in water (Stern, *Biochem. Zeitsch.* 1924, 151, 268; 1925, 159, 192).

Uric acid is not volatile: on being strongly heated it breaks up into urea, hydrocyanic acid, cyanuric acid and ammonia (Wöhler, *Pogg. Ann.* 1839, 15, 529, 619). When oxidised by strong nitric acid or potassium chlorate and hydrochloric acid, or by chlorine or bromine water in the cold, uric acid is broken down into alloxan (mesoxalylurea (*q.v.*) and urea. For cyanuric acid as oxidation product of uric acid, v. Venable and Moore (*J. Amer. Chem. Soc.* 1917, 39, 7750). Warm dilute nitric acid produces parabanic acid (oxalylurea) (*q.v.*). By the action of such oxidising agents as potassium permanganate, or ferricyanide, lead peroxide, mercuric oxide or ozone in neutral or alkaline media, uric acid yields carbon dioxide and allantoin (glyoxyldiureide) (*q.v.*). According to Behrend (*Annalen*, 1904, 333, 141) and Behrend and Schultz (*ibid.* 1909, 365, 21), the first product of oxidation of uric acid in alkaline media is *hydroxyglycoluril carboxylic acid*

which on treating (a) with an excess of alkali hydroxide takes up the elements of water, forming *ureanic acid* (dicarbaminomalonic acid)

(COOH), $\text{C}(\text{NH} \cdot \text{CO} \cdot \text{NH})_2$ (*q.v.*; see also Behrend and Zieger, *Annalen*, 1915, 410, 337; Biltz and Max, *Ber.* 1920, 53, 1964; Biltz and Robl, *ibid.* 1967); (b) with acetic acid yields potassium hydrogen *oxonate* (Strecker, *Chem. Soc. Trans.* 1875, 555); Biltz and Robl (*Ber.* 1920, 53, 1967), have shown *oxonic acid* to be identical with

When oxidised by hydrogen peroxide in alkaline solution, uric acid yields *tetracarbonimide* $\text{CO} < \begin{array}{c} \text{NH} \cdot \text{CO} \cdot \text{NH} \\ \text{NH} \cdot \text{CO} \cdot \text{NH} \end{array} > \text{CO}$ (Scholtz, *Ber.* 1901, 34, 4130), *carbonyldiurea* $\text{CO}(\text{NH} \cdot \text{CO} \cdot \text{NH})_2$ and *urea* (Schittenhelm and Wiener, *Zeitsch. physiol. Chem.* 1909, 62, 100; cf. Venable and Moore, *l.c.*; Venable, *ibid.* 1918, 40, 1099; Moore and Thomas, *ibid.* 1120; see also Ohta, *Biochem. Zeitsch.* 1913, 54, 439).

Uric acid is decomposed when fused with potassium hydroxide, yielding the potassium salts of prussic, cyanic, carbonic and oxalic acids. When heated under pressure at 160°–170° with concentrated hydrochloric or hydriodic acid, it yields carbon dioxide, ammonia and glycocholl; it is oxidised by a solution of copper oxide in ammonia (Schweizer's reagent) in the presence of potassium hydroxide to urea and oxalic acid, and a similar oxidation is effected by boiling with ferric chloride. It is decomposed by certain moulds (Kossowicz, *Bied. Zentr.* 1912, 41, 791; *Chem. Zentr.* 1912, ii, 1300, 1482; 1913, i, 640).

For the physiological properties of uric acid, its origin, and the rôle it plays in the animal economy, see *Article URINE*; also *Biochemisches Handlexikon von Aberdalden*, vol. iv. 1095–1106; and *Oxidations and Reductions in the Animal Body*, by H. D. Dakin, 92. For the influence of drugs on the elimination of uric acid from the blood, v. Abl (*Arch. Expt. Path. Pharm.* 1913, 74, 119); Denis (*J. Pharmacol.* 1915, 7, 255, 601); Folin and Lyman (*J. Pharmacol. Expt. Ther.* 1913, 4, 539); Impens (*Chem. Zentr.* 1914, 563).

Detection.—Uric acid is readily identified by the appearance of the crystals under the microscope. The most characteristic and delicate test for uric acid is the 'murexide test,' which is applied as follows: a few drops of strong nitric acid is added to the uric acid or urate and the solution evaporated to dryness on the water bath, preferably in a porcelain basin; a yellowish-red residue of alloxantin is obtained which acquires the rich purple colour of ammonium purpurate (*murexide*, *q.v.*) on moistening with ammonia, the colour changing to blue on the addition of sodium hydroxide. The nitric acid employed in the test may be replaced by chlorine or bromine water, or by a few drops of concentrated hydrochloric acid and a small crystal of potassium chlorate. Other colour reactions of uric acid are described by (1) Denigès (*J. Pharm. Chim.* 1888, [v.] 18, 161), the uric acid is oxidised to alloxan by evaporating a solution in dilute nitric acid; on adding successively to the residue a few drops of concentrated sulphuric acid and of benzene containing thiophen, a bluish coloration is obtained; (2) Ganassini (*Boll. chim. farm.* 1908, 47, 715), the uric acid or urate is suspended in water and

dissolved in 10 p.c. sodium hydroxide; subsequent saturation of the solution with potassium persulphate and the gradual addition of 10 p.c. zinc sulphate solution, until the precipitate formed no longer redissolves, causes the precipitate to assume a bluish-green colour. This test is not disturbed by the presence of proteins, other purines or pyrimidines, and may be applied for the detection of uric acid in urine or in blood. According to Vitali (*ibid.* 1911, 50, 799), sodium peroxide is the only oxidising agent that can replace the potassium persulphate in the above test, and no other metallic salt can be used instead of the zinc salt. (3) Folin and Denis (J. Biol. Chem. 1912, 12, 239), a blue coloration is developed when a solution containing 1 mg. of uric acid is mixed with 2 c.c. of a solution prepared by boiling for two hours a mixture of 100 grms. sodium tungstate, 80 c.c. of 85 p.c. phosphoric acid, and 750 grms. of water, cooling and diluting to a litre (compare Leturc, Ann. Chim. anal. 1907, 12, 194; Bass and Wiechowski, Chem. Zentr. 1913, i. 331; Obermayer, Popper and Zak, *ibid.* 658). Tests based upon the reducing properties of uric acid are the formation of a yellow, brown, or black stain of silver, when filter paper previously moistened with silver carbonate is treated with a drop of a solution of uric acid in sodium carbonate; and the reduction of Fehling solution on boiling an alkaline solution of uric acid with excess of the reagent. For the detection of uric acid in blood, Weber (Pharm. Zeit. 1912, 57, 252) recommends the following method: the blood is treated with sodium chloride and potassium phosphate to remove the proteins, the filtrate evaporated to a small bulk and saturated with ammonium chloride, the uric acid is thus precipitated as ammonium urate, which is collected and treated with a few drops of hydrochloric acid and the crystals of uric acid identified under the microscope or by the murexide test.

Estimation.—The methods of estimating uric acid in urine are based upon the precipitation of the uric acid in the form of the sparingly soluble ammonium or the double silver magnesium salt, and the subsequent determination of the uric acid in the carefully washed precipitate. Hopkins' method (Proc. Roy. Soc. 1892, 62, 93; J. Path. and Bacteriology, 1893, 1, 451), 30 grms. of ammonium chloride are added to 150 c.c. of the filtered urine previously warmed to 40° to 45°, after about an hour the precipitate of ammonium urate is collected on a small filter, washed with a 10 p.c. solution of ammonium sulphate until free from chlorine, and transferred to a beaker by means of a jet of hot water, the solution cooled and diluted with water to 100 c.c., 20 c.c. of pure concentrated sulphuric acid are added, and N/20 potassium permanganate run into the acid liquid at 60° until it acquires a pink tint permanent for some seconds and not changed by stirring. Each c.c. of N/20 permanganate solution decolorised represents 0.00375 gm. of uric acid. See Haries (Eighth Inter. Cong. App. Chem. 1912, 19, 141); Telle (Bull. Sci. Pharmacol. 1918, 25, 208).

Wärner (Zeitsch. physiol. Chem. 1900, 29, 70) recommends decomposing the washed ammonium urate with 1-2 p.c. sodium hydroxide solution, heating the solution on the water-bath

until it ceases to evolve ammonia and then determining the nitrogen in the residue by the Kjeldahl method: 1 c.c. N/10 sulphuric acid corresponds with 0.0042 gm. uric acid; Kowarsky (Berlin, Klin. Woch. 1917, 54, 987) recommends the estimation of the ammonia in the ammonium urate by the formalin method.

Folin and Shaffer's modification of Hopkins' method (Zeitsch. physiol. Chem. 1901, 32, 552) is as follows: A solution containing 500 grms. of ammonium sulphate, 5 grms. uranium acetate, and 10 p.c. acetic acid, 60 c.c. per litre is prepared, and 75 c.c. of this solution are mixed with 300 c.c. of the urine, kept for five minutes, passed through a double filter and two quantities of 125 c.c. each collected. Five c.c. of concentrated ammonia are added to each and after about 12 hours the precipitates of ammonium urate are collected and washed and the uric acid in each estimated by the permanganate method. The addition of uranium acetate is made in order to precipitate a small quantity of protein material which is otherwise thrown down on the addition of the ammonia, and which reduces permanganate. Ganasini (Boll. Chim. Farm. 1914, 53, 257) uses a modification of this method for precipitating the uric acid, which is then estimated by means of standard iodine solution, the uric acid being oxidised to alloxan, see Curtman and Lehmann (J. Biol. Chem. 1918, 26, 187).

Salkowski's method modified by Ludwig (Chem. Zentr. 1891, 390) consists in precipitating the uric acid in the urine (100 to 200 c.c.) with a mixture of ammoniacal silver solution and magnesia mixture (*cf.* Salkowski, Zeitsch. physiol. Chem. 1913, 83, 152); the precipitate containing all the uric and phosphoric acids is filtered and washed with very dilute ammonia. It is then decomposed by a warm dilute solution of potassium sulphide forming potassium urate which passes into solution, the filtrate is acidified with hydrochloric acid, evaporated to a small bulk, and the uric acid that separates on cooling is collected on a tared filter, washed with water, alcohol, ether, carbon disulphide, and again with ether, dried at 110° and weighed, see Salkowski (Zeitsch. physiol. Chem. 1913, 83, 152); Kretschmer (Biochem. Zeitsch. 1913, 50, 223); Graves and Kober (J. Biol. Chem. 1915, 20, xx.); (v. Bernard (Chem. Zentr. 1913, 1, 1364; from Bull. Sci. Pharmacol. 1913, 20, 66, for a comparative investigation of different methods; he maintains Salkowski's method gives the best results).

Folin and Shaffer (Zeitsch. physiol. Chem. 1901, 32, 552) recommend the following modification of the method in order to facilitate the removal of the silver from the silver magnesium urate; the double salt is decomposed by sulphuretted hydrogen in an acid solution containing 5 to 10 c.c. of 1 p.c. copper sulphate solution and the liquid boiled for a few minutes before filtering (*cf.* Schneller, Chem. Zentr. 1913, i. 1234).

Folin and Macallum recommend a colorimetric method for estimating uric acid in dilute solution based upon the blue colour produced when phosphotungstic acid and an alkali are added to uric acid (J. Biol. Chem. 1912, 11, 265; Folin and Denis, *ibid.* 1912, 14, 95; Brugsch and Kristeller, Chem. Zentr. 1915, i. 1090;

Benedict and Hitchcock, J. Biol. Chem. 1915, 20, 619, 629). The replacement of phosphotungstic by arsenotungstic or arseno-phosphotungstic acid gives a greater depth of colour (Morris and Macleod, J. Biol. Chem. 1922, 50, 55; Benedict, *ibid.* 1922, 51, 187; 52, 387). It is claimed that the method as modified by Benedict and Hitchcock (*ibid.* 1915, 20, 624) gives as accurate results as the titration method of Folin and Shaffer (v. Morris, *ibid.* 1916, 25, 205; Proc. Amer. Soc. Biol. 1916, xiii.; 1917, 29), who recommends precipitating the uric acid with zinc acetate in alkaline solution as a preliminary to the application of Benedict's method. See Salkowski (Zeitsch. physiol. Chem. 1913, 85, 346); Kaschiwabara, (*ibid.* 1913, 84, 223); Hüst (Zeitsch. physiol. Chem. 1915, 95, 88); Bogert (J. Biol. Chem. 1917, 31, 165); Morris (Proc. Amer. Soc. Biol. Chem. 1917, xxi.; J. Biol. Chem. 1918, 33; 1919, 37, 231); Cohen Tervaert (Arch. Néerland. physiol. 1918, 2, 337); Zaleski and Sachnowska (Russ. Physiol. J. 1919, 2, 14); Folin and Wu (J. Biol. Chem. 1919, 38, 81, 459); cf. Brown and Raiziss (J. Lab. Clin. Med. 1922, 8, 129); and Rogers (J. Biol. Chem. 1923, 55, 325); Guillaumin (J. Pharm. Chim. 1922, [vii.] 25, 5); Thiéry (*ibid.* 87); Jackson and Palmer (J. Biol. Chem. 1922, 50, 89; 53, 373).

For the rapid estimation of uric acid in urine, Vaillant (Ann. Chim. Anal. 1922, [ii.] 4, 178) titrates the liquid with a standard iodine solution made by dissolving 3.78 grms. of iodine and 15 grms. of potassium iodide in 1 litre of water. Two c.c. of this solution oxidise 0.005 grm. of uric acid to alloxan and urea. The analysis is carried out by measuring into a small tube 2 c.c. of iodine solution and 1 c.c. of carbon disulphide, and allowing the urine to fall a drop at a time from a burette, shaking the tube after each addition, until the carbon disulphide becomes first pale rose and then colourless. The uric acid content per litre of urine is calculated by dividing the number of c.c. used into 5. Sugar and small amounts of albumin do not interfere; larger amounts should be removed by heating to coagulate and then filtering. If the urine is alkaline a few drops of acetic acid are added (Chem. Soc. Abstr. 1922, ii. 668).

For the separation of and estimation of uric acid and xanthine bases by means of potassium-zinc ferrocyanide, see Thiéry (J. Pharm. Chim. 1921, 23, 494).

A colorimetric method, based on the action of uric acid on iodic acid, whereby iodine is liberated, is recommended by Autenrieth and Funk (Chem. Zentr. 1915, 1, 1918 from Münch. med. Wchschr. 1914, 61, 457); Maase and Zondek (Chem. Zentr. 1915, ii. 858). For a critical review of methods for estimating uric acid and xantho-uric substances, v. Sauzéat (J. Pharm. Chem. 5, 164, 445, 485).

Derivatives. Salts.—All four hydrogen atoms of uric acid are acidic and can be replaced by metals, as is shown by the formation of salts from each of the four trimethyl uric acids; the hydrogen atom 3 is the most acidic, then hydrogen 9, the hydrogen atoms 1 and 7 are much weaker in their acidity; hence uric acid behaves as a feeble dibasic acid (Biltz and Herrmann, Ber. 1921, 54, 1676), and forms three

series of salts, the normal urates of the type $\text{Na}_2\text{C}_5\text{H}_3\text{O}_7\text{N}_4$ are readily soluble in water and are never found in the animal system; the acid or diurates $\text{NaC}_5\text{H}_2\text{O}_7\text{N}_4$ are sparingly soluble and occur pathologically in gouty concretions; and the quadri- or hemi-urates

are more readily soluble than the diurates and are the common form in which uric acid occurs physiologically.

Normal urates may be obtained by dissolving uric acid in the theoretical quantity of alkali. They are alkaline in reaction and are decomposed by carbon dioxide, forming the acid salt. The potassium salt $\text{K}_2\text{C}_5\text{H}_3\text{O}_7\text{N}_4$ is crystalline; it dissolves with partial decomposition into the acid salt in about 36 parts of cold water; the sodium salt $\text{Na}_2\text{C}_5\text{H}_3\text{O}_7\text{N}_4\cdot\text{H}_2\text{O}$ is less soluble than the potassium salt, and is stated to be rendered more soluble by radium D (Gudzent, Zeitsch. f. klin. Med. 71, 3-6), and to be decomposed by the α -rays from radium emanation (Mesernitzky, Compt. rend. 1912, 154, 770); according to Knaff-Lenz and Wiechowski (Zeitsch. physiol. Chem. 1912, 77, 303), and to Kerb and Lazarus (Biochem. Zeitsch. 1912, 42, 82), radium has no action on the salt under sterile conditions, but accelerates the degradation of the compound in the presence of enzymes or moulds; the calcium $\text{CaC}_5\text{H}_3\text{O}_7\text{N}_4$, strontium $\text{SrC}_5\text{H}_3\text{O}_7\text{N}_4\cdot 2\text{H}_2\text{O}$, barium $\text{BaC}_5\text{H}_3\text{O}_7\text{N}_4\cdot\text{H}_2\text{O}$, and lead $\text{PbC}_5\text{H}_3\text{O}_7\text{N}_4$ salts are sparingly soluble. The mercury salt $\text{HgC}_5\text{H}_3\text{O}_7\text{N}_4$ is a white amorphous precipitate; it does not give mercuric oxide with sodium hydroxide solution and is therefore probably a lactam salt (Auld, Chem. Soc. Trans. 1907, 1046). Zinc, nickel, and copper salts are described by Curtman and Hart (J. Biol. Chem. 1921, 46, 599).

Acid or di-urates.—According to Gudzent (Zeitsch. physiol. Chem. 1909, 60, 38), uric acid forms two series of primary metallic salts (mono-sodium, potassium and ammonium urates), which differ as regards solubility. The salts of the α -series cannot be obtained pure, as at the moment of formation in water they tend to pass into the salts of the β -series. The probable cause of the change is an intramolecular rearrangement, so that the two series correspond with the two tautomeric forms of uric acid

The unstable α -salts are probably the lactam urates, and the stable β -salts the lactim urates. The α -salts have solubilities and specific conductivities that at 18° are some 33-4 p.c., or at 37° some 33-9 p.c. greater than the corresponding values for the more stable β -salts.

The sodium salt $\text{NaC}_5\text{H}_2\text{O}_7\text{N}_4\cdot 1\frac{1}{2}\text{H}_2\text{O}$ forms a crystalline powder soluble in 1200 parts of cold or 120 parts of boiling water, forming a neutral solution. The solubility of freshly percolated sodium urate at 18° is 2.03 grms. or 9.8×10^{-3} grms. molecules per litre. On keeping, or more particularly on stirring in contact with the solution, the solubility decreases and approaches that of the crystalline form. The potassium salt $\text{KC}_5\text{H}_2\text{O}_7\text{N}_4$ is amorphous

and dissolves in 800 parts of cold or 70-80 parts of boiling water; lithium salt $\text{LiC}_5\text{H}_3\text{O}_3\text{N}_4$ forms crystalline grains and is soluble in 370 parts of cold or 39 parts of boiling water; the ammonium salt $\text{NH}_4\text{C}_5\text{H}_3\text{O}_3\text{N}_4$ is soluble in 1500 parts of cold water and quite insoluble in saturated solutions of ammonium chloride or sulphate; and the magnesium

calcium $(\text{C}_5\text{H}_3\text{O}_3\text{N}_4)_2 \cdot \text{Ca} \cdot 2\text{H}_2\text{O}$, strontium

barium $(\text{C}_5\text{H}_3\text{O}_3\text{N}_4)_2 \cdot \text{Ba} \cdot 3\text{H}_2\text{O}$, and lead

salts are described. For the formation of colloidal uric acid in the presence of alkalis, see Schade and Boden (Zeitsch. physiol. Chem. 1913, 83, 347); compare, however, Lichtwitz (*ibid.* 1913, 84, 416); Schade and Boden (*ibid.* 1913, 86, 238); Gudzent (*ibid.* 1914, 89, 352); Haskins (J. Biol. Chem. 1916, 26, 205); Kohler (Z. Klin. Med. 1919, 88, 14); Schade (*ibid.* 1922, 23, 1).

The quadri-urates are difficult to obtain pure as they readily break down into diurates and uric acid; according to Rosenheim (Lancet, 1900; Zeitsch. physiol. Chem. 1911, 71, 272) and Kohler (*ibid.* 70, 360) the quadri-urates are only mixtures, in molecular proportions, of primary urates and uric acid; they are stated to exist normally in the urine and constitute the whole of the urinary excretion of birds and reptiles (v. URINE).

Adrenaline urate $\text{C}_5\text{H}_{12}\text{O}_3\text{N}_3\text{C}_7\text{H}_7\text{O}_2\text{N}_3$ forms small pointed plates (Pauly, Ber. 1904, 37, 1388). Piperazine urate $\text{C}_5\text{H}_{10}\text{N}_2\text{C}_7\text{H}_7\text{O}_2\text{N}_3$ is soluble in 50 parts of water at 17° . The phosphotungstate of uric acid forms reddish-brown cubical plates (Drummond, Bio-Chem. J. 1918, 12, 5).

Uric acid glycol

crystallises with half a molecule of water of crystallisation; it reddens at 150° and melts 165° - 168° (effervesces) (Biltz and Heyn, Ber. 1912, 45, 1877; *ibid.* 1914, 47, 459; Ann. 1916, 413, 7).

4:5-Di-methoxy-4:5-dihydrouric acid

crystallizes in slender needles, m.p. 202° - 203° (decomp.); it is reduced by sodium amalgam to uric acid and by hydriodic acid (D 146) on the water bath to ψ -uric acid (Biltz, Annalen 1916, 413, 1; Ber. 1921, 54, 2477).

p-Nitrobenzyl urate $\text{C}_5\text{H}_3\text{O}_3\text{N}_4 \cdot \text{CH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2$ melts above 350° (Lyons and Reid, J. Amer. Chem. Soc. 1917, 39, 1727).

Uric acid forms the following condensation products with formaldehyde:—

Diformaldehyde-uric acid $\text{C}_7\text{H}_5\text{O}_3\text{N}_4 \cdot 2\text{CH}_2\text{O}$ is a crystalline, sparingly soluble compound,

monobasic towards N/3 sodium hydroxide and forms a barium and a calcium salt (Weber, Pott and Pollens, Ber. 1897, 30, 2514; Annalen, 1898, 299, 340). Formaldehyde uric acid

crystallises in needles or prisms, decomposes at 37° , and forms crystalline alkali salts; and anhydroformaldehyde-uric acid

formed by dissolving diformaldehyde-uric acid in concentrated sulphuric acid and pouring the solution into ice water (Nicolai, Chem. Zentr. 1907, i, 949). For other derivatives of uric acid, v. Biltz (*l.c.*). M. A. W.

ψ -URIC ACID v. PYRIMIDINES.

URIDINE v. PYRIMIDINES.

URINE. The kidneys are compound tubular glands, and possess the power of excreting from the blood certain waste products which in aqueous solution constitute the urine. Its most important constituents are the result of the breakdown of nitrogenous materials in the body, but these substances, urea, uric acid, &c., are not actually formed in the kidneys themselves. The liver is the most important organ for their actual formation; the kidney is merely the situation where they find an exit from the body.

The characters of the urine differ greatly in different parts of the animal kingdom, according to the character of the food ingested, and the different metabolic habits of animals. The most striking difference is seen when one compares the liquid urine of mammals (in which urea is the main substance in solution) and the semi-solid urine of birds and snakes, in which urates form the preponderant constituents. In the following account attention will be in the main directed to the urine which is most familiar, namely that of man and other mammals.

A man of average weight and height, taking a normal mixed diet, passes from 1400 to 1600 c.c. (about 50 oz.) daily, and this contains about 50 grms. ($1\frac{1}{2}$ oz.) of solids. Its yellow colour varies considerably with the concentration of the urine, and is due to the presence of a number of pigments, of which urochrome (an amorphous nitrogenous substance of doubtful composition, originally so named by Thudichum) is the most abundant. Another named urobilin, a derivative of the bile pigment, is present in health in small quantities, but may be considerably increased in certain diseases.

The reaction of urine is acid; this is partly due to free acid, but mainly to acid salts, of which acid sodium phosphate is the most abundant. During digestion, however, there is a formation of free hydrochloric acid in the stomach, and a corresponding liberation of bases in the blood causes the urine to be less acid, or even alkaline. Alkaline urine is also seen in herbivorous animals and vegetarians; here the food contains excess of alkaline salts of acids such as tartaric, citric, malic, &c. These acids in the body are oxidised into carbonates which, passing into the urine, give it an alkaline reaction.

The specific gravity varies inversely as the quantity of urine passed; the quantity depends on the amount of water ingested, and also on

the amount of water that leaves the body by other channels, such as the skin. It varies normally from 1.015 to 1.025. A sp.gr. below 1.010 should excite suspicion of hydruria; one over 1.030 of a febrile condition, or of diabetes, in which disease it may rise to 1.050. The sp.gr. has, however, been known to sink as low as 1.002 (after large potations, *urina potus*), or to rise as high as 1.035 (after great sweating) in perfectly healthy people.

When a normal urine is distilled, an unknown, or imperfectly known, substance begins to volatilise at 60°-70°C., but does not completely leave the urine until the boiling-point is reached. The distillation is carried out on the urine which has been acidified with phosphoric acid: at least one-quarter of the urine should distil over. This distillate is a limpid colourless liquid of intense urinous odour, and is neutral to all reagents. It is not precipitated by alkalis or acids, nor with the bicarbonate and sublimate mixture; it does not react with Fehling's solution, nor give the diazo reaction in neutral or acid media; no apparent change takes place with salts of silver, cadmium, iron, lead, mercury, or zinc. With Nessler's reagent it gives a greenish-yellow precipitate similar to that given with many other substances, such as alkaloids, amides, all amines, organic ammonias, aldehyde and methylene derivatives. It is concluded that there is a volatile body in normal urine resembling ketone, but different from ordinary acetone, precipitated by Nessler's reagent, and that it is to this substance that the characteristic odour of the urine is due (E. Pittarelli, *La Riforma Med.* May 14th, 1923, through *Lancet*, June 9th, 1923, 1172).

The following table gives the average amounts of the urinary constituents passed by a man taking an ordinary diet containing about 100 grms. of protein in the 24 hours—

Total quantity of urine	1500	grms.
Water	1400	"
Solids	60	"
Urea	35	"
Creatinine	0.9	"
Uric acid	0.75	"
Hippuric acid	1.0	"
Ammonia	0.65	"
Sodium chloride	16.5	"
Phosphoric acid	3.5	"
Sulphuric acid	2.0	"
Chlorine	11.0	"
Potassium	2.5	"
Sodium	5.5	"
Calcium	0.26	"
Magnesium	0.21	"

The most abundant constituents are, therefore, water, urea, and sodium chloride. We will take the most important individual constituents one by one.

Urea. The time-honoured formula of urea as carbamide $\text{CO} \begin{smallmatrix} \text{NH}_2 \\ \text{NH}_2 \end{smallmatrix}$ must be replaced according to Werner by the cyclic formula

This offers a satisfactory explanation for the behaviour of urea during hydrolysis. It was first prepared synthetically

by Wöhler (1828) from its isomeride ammonium cyanate.

It crystallises in the dimetric system, and is readily soluble in water and in alcohol; it has a faint saltish taste, and is neutral to litmus. When treated with nitric acid, octahedra, or lozenge-shaped tablets are formed of urea nitrate ($\text{CON}_2\text{H}_4 \cdot \text{HNO}_3$); when treated with oxalic acid prismatic crystals of urea oxalate

are formed.

Under the influence of certain micro-organisms which grow readily in stale urine, it is converted into ammonium carbonate

Hence the ammoniacal odour of putrid urine. In the soil the urinary ammonia is converted into nitrates by nitrifying organisms (*see SOILS*).

By means of nitrous acid, urea is broken up, as shown in the following equation:

Sodium hypobromite decomposes urea as follows:

A critical examination of this reaction shows that there is always a deficit in the quantity of urea found, whether it is calculated from the volume of the nitrogen liberated, the carbon dioxide formed, or the hypobromite used. Side reactions of a complex nature also occur under usual conditions, giving rise to a small amount of CO. Moreover, other urinary constituents (uric acid, creatinine, &c.) also yield nitrogen under the conditions of the experiment. Hence the method which was formerly much used for the estimation of urea is now abandoned when accuracy is required. The methods at present in use are those in which the urea is decomposed into ammonia and carbon dioxide; the ammonia formed is estimated, but as the urine contains a small amount of preformed ammonia this has to be previously estimated and deducted from the total. The methods of Mörner and Sjöquist, Folin and others (*v. UREA*) are examples of this type of estimation, but the enzymatic method depending on the action of the enzyme urease contained in soy-beans promises to replace all other methods. It was introduced by Marshall. Urease is a specific enzyme, which rapidly and quantitatively decomposes urea at 35°-40°C. into ammonia and carbon dioxide. The ammonia formed is driven off in a suitable apparatus by a current of air, absorbed with standard acid, and estimated by titration, alizarin-red or methyl-orange being used as indicator.

The quantity of urea is practically uninfluenced by muscular work, but depends mainly on the amount of protein ingested. The amino acid fragments formed by the digestion of protein are utilised in two ways. A small portion is used by the tissue cells to repair their waste. In time this will be catabolised and the waste products discharged as urea, ammonia, creatinine, &c. The amount of such *endogenous* metabolism is constant. The other and larger part of the cleavage products of the food proteins are deaminised and converted into urea by the liver, the non-nitrogenous fatty residue being

burnt, and so utilised as a source of heat and other forms of energy. This part of metabolism is termed *exogenous*. Urea excretion is usually at a maximum about 3 hours after a meal. The conversion of amino acids into urea is, in part at any rate, due to enzymic action; e.g. arginase is an enzyme which converts arginine (one of the more complex amino acids resulting from protein disintegration) quantitatively into urea and ornithine (di-amino-valeric acid). There is also no doubt that ammonia is an important intermediate between such amino acids as glycine (amino-acetic acid), leucine (amino-caproic acid), &c., and the final product urea. Ammonia so liberated unites with the carbon dioxide of the blood, and ammonium carbonate and carbamate are thus formed. The close relationship of these two salts to urea is apparent from their formulae—

This view, though simple, must be modified if Werner's conception of the structure of urea is accepted.

A small quantity of ammonia always slips through into the urine, because a small quantity of the ammonia-containing blood passes through the kidney before reaching the organ (the liver), which is capable of converting it into urea. Acids are very toxic to the body, and the defence of the body against acids (administered as such, or produced in pathological metabolism, e.g. fatty acids in diabetes) is an increase of ammonia formation, or to put it more correctly, less of the ammonia formed is converted into urea.

Creatine and creatinine.—Creatine is an abundant constituent of muscular tissue; *in vitro* by boiling it with baryta it takes up water and splits up into urea and methyl-glycine, as shown in the following equation—

Creatine, however, is absent from normal urine, and only occurs in starvation and in other conditions, in which there is a rapid loss of muscular tissue. Its normal fate in the body is unknown, since creatine injected into the circulation leaves the body in the urine unchanged, and leads to no increase of urea.

It also is not converted into creatinine, which was formerly held to be its fate. Here, again, we have an instance of reactions, which occur *in vitro*, but not *in vivo*. Creatinine is a crystalline, strongly basic substance, which chemically is creatine *minus* a molecule of water. It is always present in the urine, and next to urea, is its most abundant nitrogenous constituent. Mellanby believes that certain products of protein catabolism, the nature of which is uncertain, are carried to the liver, and from these the liver forms creatinine; this is transported to the muscles, and there stored as creatine, excess being then eliminated in the urine. The small amount of creatinine excreted in liver disease favours the view that the liver is the great agent in its production, as it is in that of urea and uric acid. In health the amount of creatinine is very constant, and is not influenced by diet or muscular exercise.

Uric acid ($\text{C}_5\text{H}_4\text{N}_4\text{O}_6$) is excreted as urates in mammals in small quantities only, but in birds and serpents is the principal nitrogenous constituent of their urine. It can be readily prepared from the latter urine, in which it is mainly present as the acid ammonium urate, by dissolving it in sodium hydroxide and precipitating with hydrochloric acid. It crystallises in rectangular plates and prisms. Uric acid dissolves in pure water in the proportion 1 : 15,000 (Gudzent), and at 18° in the proportion 1 : 39,500 (His and Paul). On oxidation it yields urea and oxalic acid, alloxan ($\text{C}_8\text{H}_2\text{N}_4\text{O}_4$) or allantoin ($\text{C}_4\text{H}_6\text{N}_4\text{O}_3$), being intermediate products, according to the oxidising agent employed. It can be best identified by the *murexide* reaction, which consists in evaporating to dryness with nitric acid; the yellowish-red residue gives, on the addition of ammonia, the violet ammonium purpurate.

Uric acid does not contain the COOH group which is typical of organic acids, and in aqueous solution its reaction is neutral. Nevertheless one of its hydrogen atoms is replaceable by a metallic radicle, and it acts therefore as a monobasic acid, and forms *primary* salts (mono- or acid urates). In the presence of strong bases it forms *secondary* salts (di-urates); these only exist in the solid condition or in the presence of strong alkali. By water they are at once decomposed forming primary salt and alkali. A third series of salts (quadri-urates) was formerly assumed to exist, but these are merely mixtures of uric acid and primary urate.

In water, urine and blood, we have therefore only to deal with primary urates. It has been shown that the primary sodium urate

occurs in two modifications, the α - and the β -forms. The unstable α salt is gradually transformed in aqueous solution into the stable β salt, owing to an intramolecular change. These two salts correspond to two tautomeric modifications of uric acid, the lactam form (formula I) giving rise to the unstable, and the lactim form (formula II) to the stable salt.

These facts have a bearing on gouty conditions; normally the small amount of urate in the blood is held in solution. In gout the amount is increased, and the excess is probably in the unstable α -form. The conversion of this into the β -form gives rise to the deposition of urates in the tissues which occurs during the course of the attack.

The quantity of uric acid excreted by an adult varies from 0.5 to 0.75 gm. daily. The method used for estimation is based on Hopkins' discovery, that when the urine is saturated with an ammonium salt (chloride or sulphate), all the uric acid is precipitated as ammonium urate; this is collected and the uric acid in it determined. The Folin-Shaffer method is founded on this reaction. Folin has also introduced a colorimetric method, which depends on the

blue colour uric acid strikes with phosphotungstic acid (*v. URIC ACID*).

In birds uric acid originates from the combination of ammonia and lactic acid. In mammals it mainly arises from the purine bases of the food, which are cleavage products of nucleic acid, the main constituent of the nuclei of the body cells. In this process several tissue enzymes come into play; first nuclease liberates adenine (amino-purine $C_5H_5N_3.NH_2$) and guanine (amino-oxypurine $C_5H_4N_4O.NH_2$) from nucleic acid; then 'deaminising' enzymes convert adenine into hypoxanthine (monoxypurine $C_5H_4N_4O$) and guanine into xanthine (dioxypurine $C_5H_4N_4O_2$); oxidases step in next and convert hypoxanthine into xanthine, and xanthine into uric acid (trioxypurine $C_5H_4N_4O_3$). The liver is the principal seat of these transformations, and in some animals some of the uric acid so formed is destroyed in the same organ, and appears as allantoin and urea. So far as tissue extracts can give a true picture of metabolism *in vivo* the human tissues are destitute of the uricolytic (uric acid destroying) enzyme)

Small quantities of purine bases are found in the urine in addition to uric acid.

Hippuric acid ($C_9H_9NO_3$) in the form of hippurates is present in small quantities in the urine of man, but is specially characteristic of herbivorous urine. This is due to the food of herbivora containing substances of the benzoic acid group. The condensation of benzoic acid with glycine to form hippuric acid appears to occur in the kidney itself, and may be represented by the following equation—

For the estimation of hippuric acid in urine, see Snapper and Laquer, Archives Néerlandaises de Physiologie, 1921, 6, 48, which contains further references to the literature of the subject.

Kynurenic and urocanic acids are present in small quantities in dog's urine. Kynurenic acid $C_{10}H_9NO_3$ is hydroxyquinoline carboxylic acid ($HO.C_6H_4.N.COOH$) and originates from one of the decomposition products of protein called tryptophan (indole-amino-propionic acid). Urocanic acid ($C_{10}H_9N_2O_4$) is a rarer constituent, and its origin in the body is not clear.

Inorganic constituents of urine. The principal salt is *sodium chloride*, and its amount varies with that in the food. The *sulphates* present are principally those of sodium and potassium. They are derived from the metabolism of protein, and their excretion, although it occurs earlier than that of urea, runs parallel with it. About one-tenth of the total sulphates are ethereal sulphates, such as potassium phenyl sulphate and potassium indoxyl sulphate (urinary indican); the organic radicles originate from protein putrefaction in the alimentary canal, and abnormally great putrefactive processes there lead to an increase in the excretion of such sulphates. Sulphur is also present in the form of less highly oxidised organic compounds, usually spoken of as 'neutral sulphur,' a term which includes thioacetic acid and its salts, taurine, cystine, methyl mercaptan.

Carbonates are only present in alkaline urine. Alkaline and earthy *phosphates* are also present and small quantities of organic phosphates, for instance, glycerophosphates. They arise partly from the food, but chiefly from the metabolism of organic phosphorised constituents of the body, such as nucleic acid, lecithin, and other phosphorised fats (phosphatides).

According to Amberg and Mayer (Amer. J. Physiol. 1922, 60, 564) minute quantities of citric acid occur in normal human urine.

Abnormal constituents of urine. The most commonly occurring of these are albumin (in Bright's disease) and other proteins, dextrose, acetone, aceto-acetic acid, and β -hydroxybutyric acid in diabetes, lactose in nursing mothers, bile in jaundice, blood when hæmorrhage occurs in any part of the urinary tract, hæmoglobin, and certain derivatives of hæmoglobin in black water fever and other pathological states, and pus as the result of suppuration in any part of the urinary tract.

Urinary deposits. Normal urine is clear except for a faint cloud of mucus. Formed or anatomical elements such as blood corpuscles, pus corpuscles, bacteria, entozoa, &c., may be present in various pathological conditions, and are identified by microscopic examination. A special chemical interest attaches, however, to crystalline deposits, and without entering into any discussion of the medical reasons that lead to their appearance, these may be briefly enumerated as follows:—

A. In acid urine may be found—

1. Uric acid, as whetstone, dumb-bell, or sheaf-like aggregations of crystals deeply tinged with urinary pigment, looking like cayenne pepper.

2. Urates. These are generally amorphous. The acid urate of sodium and ammonium may sometimes occur in star-shaped clusters of needles or spheroidal clumps with projecting spines. The deposit has the appearance of brick-dust, as it is coloured by one of the urinary pigments (uroerythrin). This deposit dissolves on warming the urine.

3. Calcium oxalate in the form of octahedral crystals insoluble in acid.

4. Cystine (diamino-dithio-lactic acid $C_6H_{12}N_2S_2O_4$) in colourless hexagons; a rare condition often hereditary.

5. Calcium phosphate $CaHPO_4.2H_2O$, rare.

6. Leucine (amino-caproic acid) and tyrosine β -p-hydroxyphenyl- α -aminopropionic acid, rare.

B. In alkaline urine we may find—

1. Phosphates; calcium phosphate

which is amorphous; triple phosphate

in 'coffin lid' crystals or feathery stars; calcium hydrogen phosphate $CaHPO_4$ in rosettes, spherules, or dumb-bells; magnesium phosphate $Mg_3(PO_4)_2$ in long plates. All are soluble in acetic acid without effervescence.

2. Calcium carbonate $CaCO_3$, biscuit-shaped crystals, common in herbivorous urine, soluble in acetic acid with effervescence.

3. Ammonium urate $C_5H_8(NH_4)_2N^+O_2$, 'thorn apple' spherules.

4. Leucine and tyrosine, very rare.

Of these deposits, urates in acid urine, and phosphates in alkaline urine are the commonest; these are not necessarily pathological; thus urates may form in the urine when it cools, especially if that secretion is concentrated, e.g. after sweating profusely. Urine, when it becomes alkaline, always deposits phosphates, and the alkaline urine of herbivora is always thick for that reason.

Urinary calculi. Concretions called sand, gravel, and stones, according to their size, may form in the kidney, the ureter, or in the bladder. They result from the conglomeration of urinary deposits, the deposition occurring in concentric layers. The substances deposited in acid urine are most frequently uric acid, urates or calcium oxalate, or a mixture of these materials; in alkaline urine, phosphates. If the reaction of the urine changes during the formation of the calculus alternate layers of these two sets of materials will be found. The uric acid calculus is generally regarded as the commonest form of stone in the bladder, but in renal calculi, as B. Moore has shown, the most abundant constituent is calcium oxalate, frequently mixed with calcium phosphate, the second constituent in frequency and abundance. Calcium is practically the only base associated with oxalic acid, phosphoric acid, and in less amount with uric acid. All these acids form highly insoluble salts with calcium. Oxalic and uric acids are associated products in metabolism, and occur in cases of incomplete oxidation.

The physical properties of a calculus—colour, hardness, smoothness, or roughness, &c.—give little or no clue to its chemical nature. A chemical analysis is always necessary, and this gives valuable indications for after treatment; for instance, in renal calculi, consisting of calcium oxalate, the treatment should be designed to diminish alkalinity, to avoid calcium-rich foods, and to induce the taking of exercise to promote oxidation in the body.

There are, in addition to these common forms of stone, others of a rarer kind, and a list of the different varieties of calculus is as follows—

1. Those composed of uric acid or urates with little or no admixture with phosphates.

2. Mixed calculi, like the preceding, but containing often in alternate layers a large quantity of phosphate.

3. Calcium oxalate calculi, often containing small quantities of phosphates and urates.

4. Phosphate calculi: a stone composed of pure calcium phosphate is rare; a nucleus of uric acid is generally present.

5. Calcium carbonate calculi are those generally found in the prostate.

6. Cystine calculi are mostly small, smooth, and have a yellow tinge, turning to green on exposure to air. These are rare.

7. Xanthine calculi are still rarer.

8. Fibrinous calculi composed of fibrin or inspissated albumin, have a glassy appearance on fracture; blood calculi have been described in cases of renal hæmaturia; 'urostealth' calculi have been described, and consist of fatty acid with more or less cholesterol. One case of 'is-ligo' calculus has been described.

No attempt has been made in the foregoing outline sketch of the chemical properties of the

urine in health and disease to give complete bibliographical references. The literature of urine is enormous, and those interested in it should consult standard works on physiology, physiological chemistry, pathology, and medicine. One of the most trustworthy handbooks on the urine only, and containing abundant references to literature, is Neubauer and Vogel's *Analyse des Harns*, edited by Huppert, Wiesbaden, C. W. Kreidel.

URINOD C_8H_8O , a pale yellow oil, obtained from urine, slightly heavier than water, b.p. $108^\circ/23$ mm.; possessing a very penetrating, persistent and disagreeable odour and to which the characteristic smell of urine is due. Is readily volatile with steam, reduces potassium permanganate and ammoniacal silver nitrate in the cold, and reacts with Millon's reagent, but not with Barreswil's (Fehling's) solution, or solution of alkali picrate. The dinitro-derivative, m.p. 78° , forms golden needles. Urinod acts with semicarbazide with production of a compound, m.p. 254° , which crystallises in thin, hexagonal leaflets. When urinod is treated with bromine, two compounds are produced; one of these has m.p. about 110° , whilst the other is not melted at 250° . The compound probably has the structure of cyclohexene-4-one

or the quinonoid constitution

Urinod does not occur in the free state in urine, but exists in a conjugated form, and is liberated by fermentation, or by the action of dilute sulphuric acid. It is very toxic, and may have some connection with uræmia (Dehn and Hartman, J. Amer. Chem. Soc. 1914, 36, 2136).

URISOL. Syn. for hexamethylenetetramine.

URITONE (hexamine). Syn. for hexamethylenetetramine.

UROCITRAL, UROPHENIN, v. SYNTHETIC DRUGS.

URODONAL. Trade name for a preparation of hexamethylenetetramine, piperazine quinate and methylglyoxalidine.

UROGENIN. Trade name for an addition product of theobromine and lithium hippurate.

UROL. Trade name for uric quinate.

UROPHERIN v. SALICYLIC ACID.

UROPURGOL (helmitol, neurotine, formamol). The hexamethylenetetramine salt of anhydromethylene-citric acid.

UROSIN. Trade name for lithium quinate.

UROTROPIN. Hexamethylenetetramine, v. SYNTHETIC DRUGS.

UROXANIC ACID, dicarbaminomalonic acid $(CO_2H)_2C(NH \cdot CO \cdot NH_2)_2$, is prepared by the gradual oxidation of uric acid in alkaline solution by the oxygen of the air (Städeler, Annalen, 1851, 78, 286; Strecker, *ibid.* 1870, 155, 177; Biltz and Robl, Ber. 1920, 53, 1950); by oxidising an alkaline solution of uric acid with 5 p.c. potassium permanganate solution (1 atom of oxygen to 1 mol. of uric acid) (Behrend, *ibid.* 1904, 333, 152; Sundvik, Zeitsch. physiol. Chem. 1904, 41, 343; Behrend and Schultz, *ibid.* 1909, 365, 21; Biltz and Robl, *l.c.*).

For the mechanism of the formation of uroxanic acid from uric acid, see Biltz and

Max (Ber. 1920, 53, 1964). The two carbamido groups in uroxanic acid can be quantitatively eliminated by sodium nitrite with the formation of mesoxalic acid (Biltz and Robl, l.c.).

Uroxanic acid crystallises in indistinct tetrahedra (decomp. 162°); it is sparingly soluble in cold water and insoluble in alcohol; it is a strong dibasic acid and its normal alkali salts are neutral towards litmus and phenolphthalein. It readily loses CO_2 and yields allantonic acid when shaken for several days with cold 95 p.c. methyl alcohol. When heated with water it breaks down into allanturic acid

mesoxalic acid and urea. The aniline and hydroxylamine salts are sparingly soluble; the latter, melts at 155° ; the normal phenylhydrazine salt, $(\text{C}_6\text{H}_5\text{O}_4\text{N}_4 \cdot 2(\text{C}_6\text{H}_5\text{N}_2))$ crystallises in colourless plates, m.p. 130° – 132° (decomp.), when boiled with water it is decomposed, yielding the phenylhydrazine salt of mesoxalic acid phenylhydrazone $\text{C}_{18}\text{H}_{16}\text{O}_4\text{N}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, this forms yellow needles that melt at 154° – 158° , solidify at 160° and then decompose at 183° . The normal silver, sodium, barium, and calcium salts of uroxanic acid are crystalline.

The potassium salt forms colourless crystals, $a:b:c=0.88576:1:1.2044$, and gives hydrates containing 3.5, 3, and probably 0.5, H_2O ; the ammonium salt decomposes at 182° . The methyl ester decomposes at 213° , and is converted by boiling water into spirodihydantoin, which yields the di-silver salt $\text{C}_8\text{H}_2\text{O}_4\text{N}_4\text{Ag}_2 \cdot 2\text{H}_2\text{O}$ and the diammine copper salt

(Biltz and Robl, l.c.).

For the physiological action of uroxanic acid, see Saiki (J. Biol. Chem. 1910, 7, 263).

M. A. W.

URSAL. Ureasalicylate. A uric acid eliminant.

URSOL v. *p*-PHENYLENEDIAMINE.

URSOL v. *p*-AMINOPHENOL.

URSONE. *Ursone*. A white crystalline optically active substance $\text{C}_{28}\text{H}_{47}\text{O} \cdot \text{COOH} \cdot 2\text{H}_2\text{O}$, m.p. 273° , $[\alpha]_D^{15} = +58^{\circ}$, found in holly, maté, and other species of *Ilex*, and in many ericaceous plants. With sulphuric acid it gives an orange-yellow colour with green fluorescence; an acetic anhydride solution gives with sulphuric acid a red coloration passing to violet, green, and blue; a chloroform solution shaken with an equal volume of sulphuric acid colours the latter

yellow. Soluble in ethyl and methyl alcohols, chloroform, carbon disulphide, ether, and ethylene bromide. Yields a readily crystallisable methyl ester (Dodge, J. Amer. Chem. Soc. 40, 12; Nooyen, Pharm. Weekblad. 1920, 57, 1128). According to van Der Harr (Rec. trav. chim. 1924, 43, 387) urson has the formula $\text{C}_{31}\text{H}_{50}\text{O}_8$, m.p. 279° – 280° , and gives sesquiterpene and CO_2 on distillation with zinc dust. It forms an acetyl derivative, m.p. 201° , a methyl ester, m.p. 165° , and an acetyl derivative of the methyl ester, m.p. 245° . It thus appears to contain a hydroxyl and a carboxyl group.

URUSHIOL v. LACQUER; RESINS. Cf. Majima, Ber. 1922, 55 [B.] 172; Levin, J. Amer. Med. Assoc. 1924, 465; Pharm. J. 1924, 112, 236.

USNIC ACID $\text{C}_{18}\text{H}_{16}\text{O}_7$ (Stenhouse, Proc. Roy. Soc. 18, 222), $\text{C}_{18}\text{H}_{16}\text{O}_8$ (Paterno, Ber. 9, 345). An acid found in certain lichens (v. LICHENS).

UVANITE. Hydrated uranium vanadate $2\text{UO}_3 \cdot 3\text{V}_2\text{O}_5 \cdot 15\text{H}_2\text{O}$, crystallised in the orthorhombic system. It occurs as a brownish-yellow powder disseminated in sandstone at Temple Rock in Emery Co., Utah. In appearance and mode of occurrence it thus resembles carnotite (*q.v.*), but it has not the clear yellow colour characteristic of carnotite. The mineral dissolves readily in a solution of ammonium carbonate. The name uvanite is a contraction of the words uranium and vanadium with the mineralogical termination *ite*. (F. L. Hess and W. T. Schaller, 1914.) L. J. S.

UVAROVITE v. GARNET.

UVITONIC ACID v. BONE OIL.

UZARA. The root of a species of *Gomphocarpus* (N.O. *Asclepiadaceae*) is used by medicine men in the region of the great African lakes against diarrhoea. The action of an extract was first described by Gürber (Muench. Med. Wochenschr. 1911, 58, 2100) and was found to be specific on the intestine, resembling that of opium, but without the undesirable after effects of the latter drug. A dried alcoholic extract has been placed on the market in Germany under the name uzaron. According to Hennig (Arch. Pharm. 1917, 255, 382) the active principle is the glucoside *uzarin* (5 p.c. of the root) $\text{C}_{78}\text{H}_{108}\text{O}_{30} \cdot 9\text{H}_2\text{O}$, relatively well soluble in water and hydrolysed by acids into one molecule of propyl alcohol, three of dextrose and three of *uzaridin* $\text{C}_{18}\text{H}_{22}\text{O}_8$, which is strongly bitter. The glucoside is only slightly bitter. Cf. Kofler, Arch. Pharm. 1917, 255, 550; and Holmes, Pharm. J. 1920, 507. G. B.

V

VALAMIN. Trade name for the isovaleric ester of tertiary amyl alcohol.

VAL D'ARNO SUPERIORE RESIN v. RESINS.

VALEARIN. Trade name for valeryl trimethylammonium chloride.

VALENTINITE. Antimony trioxide Sb_2O_3 , crystallised in the orthorhombic system and dimorphous with senarmonite (*q.v.*). The small tabular or prismatic crystals are often arranged in fan-shaped groups. They have perfect cleavages in three plane directions (the unit prism and the brachypinacoid) parallel to the

vertical axis, and consequently broken surfaces present a fibrous aspect with pearly lustre. They are white or greyish, translucent, adamantine in lustre, very soft (H. 2), and readily distorted. Sp.gr. 5.76. The mineral occurs in the upper oxidised portions of lodes, having resulted by the alteration of stibnite and other antimony minerals. It is found at Bräunsdorf in Saxony, Příbram in Bohemia, Malaczka in Hungary, Algeria, Bolivia, &c. L. J. S.

VALERIAN. The root of *Valeriana officinalis* (Linn.) yields on distillation with water an essential oil of a pale yellow or greenish colour,

having a strong smell of valerian, an aromatic taste, and acid reaction; sp.gr. 0.90-0.93. Thickens at -15° , and begins to boil at about 200° . Consists of a mixture of valeric acid, a camphene, a stearoptene, and a resin (Pierlot, Ann. Chim. [iii.] 56, 291; Gerhardt, *ibid.* [iii.] 7, 275).

Valerian root contains two alkaloids: *chatinine* and *valerine*. One kilo of the fresh root yielded only 0.10 grm. of mixed alkaloids, chatinine predominating (Goris and Vischniac, Compt. rend. 1921, 172, 1059).

For the assay of Valerian Root, see Bullock, Pharm. J. 1924, 113, 109.

VALERIC or PENTOIC ACIDS C_5H_9COOH .

Four isomerides are known.

1. *n*-Valeric acid $CH_3(CH_2)_3COOH$, is found in pyroligneous acid, and occurs free and as esters in the animal and vegetable kingdoms, chiefly in the roots of *Valeriana officinalis* (Linn.) and of *Archangelica officinalis* (Hoffm.), from which it may be isolated by boiling with water or sodium hydroxide. It may be obtained by boiling *n*-butyl cyanide with potash (Lieben and Rossi, Annalen, 159, 58); by oxidation of α -hydroxycaproic acid (Erlenmeyer, Ber. 1876, 1840); by reduction of laevulinic acid (β -acetylpropionic acid) with phosphorus iodide or sodium amalgam (Kehrer and Tollens, Annalen, 206, 233; Fittig and Wolff, *ibid.* 208, 109); by heating propylmalonic acid (Juslin, Ber. 1885, 2504); by the fermentation of calcium lactate (Fitz, *ibid.* 1890, 1309); and by the action of CO_2 on magnesium *n*-butyl bromide (Gilman and Parker, J. Amer. Chem. Soc. 1924, 46, 2816; Chem. Soc. Abstr. 1925, 128, i, 228). A colourless oil having a disagreeable smell, b.p. 186° - 186.4° (Fürth, Monatsh. 9, 310); sp.gr. 0.9415 at $20^{\circ}/4^{\circ}$ (Lieben and Rossi); 1 vol. of acid dissolves in 27 vols. of water at 16° .

Methyl valerate boils at 127.3° , *ethyl valerate* at 144.6° (736.5 mm.), and *isobutyl valerate* at 167.0° - 168.5° ; sp.gr. 0.8544 $20^{\circ}/4^{\circ}$.

2. isoValeric acid, β -methylbutyric acid

Discovered in 1817 by Chevreul in dolphin oil from *Delphinus globiceps* and *D. phocaena*, and termed by him *phocenic acid* (cf. André, Compt. rend. 1924, 178, 1188; J. Soc. Chem. Ind. 1924, 43, 479). Found in other fish oils and in perspiration. In the roots of *Valeriana officinalis* (Linn.), *Archangelica officinalis* (Hoffm.), and in the berries of *Viburnum Opulus* (Linn.). Formed in the putrefaction of albuminoids; by the oxidation of glue, oleic acid, fats, and fusel oil (Lawkrow and Jazukowitsch, J. 1864, 337; Pierre and Pouchet, Ann. Chim. [iv.] 29, 229; Koizumi and Ichinose, Japan. Pat. 41910; Chem. Soc. Abstr. 1924, 126, i, 259). Prepared by the action of alcoholic potash on isopropyl cyanide, and by long boiling of amyl alcohol with sodium methoxide (Guerbet, Compt. rend. 128, 512). Colourless oily liquid, smelling like valerian root and putrid cheese; b.p. 173.7° (Kahlbaum, Ber. 1883, 2480), sp.gr. 0.931 at 20° . Soluble in 23.6 parts of water at 20° . The valeric acid of pharmacy is prepared from valerian root or from amyl alcohol. The ammonium and zinc valerates are also used in medicine.

For quantitative estimation of isovaleric acid

in the presence of acetic acid, v. Chapman, Annalen, 1899, 114.

Methyl isovalerate boils at 116.7° , and *Ethyl isovalerate* at 134.3° .

isoAmyl isovalerate $C_5H_{11}O(C_4H_9O)$; b.p. 194° ; dissolved in spirits of wine is used in confectionery as *essence of apples*.

3. α -Methylbutyric acid $CH_3\cdot CH(C_2H_5)COOH$ is found in the oil of *Archangelica officinalis* (Hoffm.) (Ciamician and Silber, Ber. 1896, 1815), and may be obtained by heating methyl-crotonic acid (tiglic acid) with hydriodic acid (Schmidt and Berendes, Annalen, 191, 117); by the action of sodium amalgam on bromomethyl-ethyl-acetic acid in a sulphuric acid solution (Fagenstecher, *ibid.* 195, 109); and by heating methyl ethyl-malonic acid (Conrad and Bischoff, *ibid.* 204, 151). On oxidising optically active amyl alcohol, a mixture of isovaleric and α -methylbutyric acids is obtained which can be separated by converting them into their silver salts, silver isovalerate being six times less soluble in water than silver α -methylbutyrate (Erlenmeyer and Hell, Annalen, 180, 301; Conrad and Bischoff, *ibid.* 204, 157). A colourless somewhat mobile liquid; b.p. 173° - 174° , sp.gr. 0.938 at $20^{\circ}/20^{\circ}$ (Schütz and Marckwald, Ber. 1896, 26).

4. $\alpha\alpha$ -Dimethylpropionic acid $(CH_3)_2C\cdot COOH$. Obtained by heating trimethyl-acetonitrile with strong hydrochloric acid (Butlerow, Annalen, 170, 151; 173, 355); or by the oxidation of pinacolin (Butlerow, l.c.; Friedel and Silva, Ber. 6, 146, and 816). Crystallises in the regular system; m.p. 34° - 35° , b.p. 163° (Sudborough and Lloyd, Chem. Soc. Trans. 1899, 475), sp.gr. 0.905 at 50° ; soluble in 45 parts of water at 20° .

VALEROBROMINE $(CH_3)_2CH\cdot CHBr\cdot COONa$. Obtained by hydrolysing and neutralising the product formed by the action of bromine on valeric acid. Used as a sedative.

VALEROPHEN. Methyl ester of phenolphthalein.

VALERYDIN, VALIDOL, VALISAN, VALYL, v. SYNTHETIC DRUGS.

VALINE, α -aminoisovaleric acid

was isolated first by Gornp-Besanez (Annalen, 1856, 98, 1) from the pancreas of the ox, and occurs in the young seedlings of *Lupinus luteus* (L.), *Lupinus albus* (L.), *Lupinus angustifolius* (L.), *Vicia sativa* (L.), the etiolated seedlings containing more than the green plants (Schulze and Barbieri, J. pr. Chem. 1883, [i.] 27, 33 7; Schulze and Winterstein, Zeitsch. physiol. Chem. 1902, 35, 308; Schulze, *ibid.* 1894, 20, 306; 1896, 22, 423; Schulze and Castoro, *ibid.* 1903, 38, 199; Wassilieff, Landw. Versuchsstat. 1901, 55, 45; Schulze, Zeitsch. physiol. Chem. 1893, 17, 193; Menozzi, Ber. 1888, 21, 619); in zeln (Osborne and Clapp, Amer. J. Physiol. 1908, 20, 470); Dakin (J. Biol. Chem. 1924, 61, 137); in Emmenthaler cheese (Winterstein, Zeitsch. physiol. Chem. 1904, 41, 500). Valine is one of the products of hydrolysis of such proteins as horn, keratin, edestin, etc., and occurs together with leucine and proline in the fraction of esters, b.p. 60° - $90^{\circ}/10$ mm.; it is formed in the autolysis of the pancreas and liver, and in peptic and tryptic digestion (Fischer and Dörpinghaus, *ibid.* 1902, 36, 462; Abderhalden and Voitino-

vici, *ibid.* 1907, 52, 348; Levene and van Slyke, J. Biol. Chem. 1909, 6, 419; Levene, Zeitsch. physiol. Chem. 1904, 41, 393; Lawrow, *ibid.* 1901, 33, 312). The valine occurring naturally is the dextrorotatory form; the racemic form was prepared first synthetically by Fittig and Clark (Annalen, 1866, 139, 200) by the action of concentrated ammonia on α -bromoisovaleric acid at 100°; and later by Lipp (*ibid.* 1880, 205, 1) by hydrolysing the aminoisovaleronitrile obtained by the condensation of isobutyraldehyde with ammonia and hydrocyanic acid. It is prepared most conveniently, and the yield is 70 p.c. of the theoretical, by Slimmer's modification of Fittig and Clark's method (Ber. 1902, 35, 400); 500 grms. of α -bromoisovaleric acid with 1500 grms. of aqueous ammonia saturated at 15° and 500 grms. of powdered ammonium carbonate are heated in an autoclave at 100° for eight hours; the resulting brownish liquid is filtered and evaporated to one-third its bulk, when most of the amino acid crystallises out. The rest is obtained in the form of its hydrochloride by acidifying the mother liquor with hydrochloric acid, evaporating to dryness and extracting the residue with 80 p.c. alcohol.

Racemic valine can be resolved into its optically active isomerides by the fractional crystallisation of the brucine salt of the formyl derivative; the brucine salt of formyl-*l*-valine being less readily soluble in methyl alcohol than is the corresponding salt of formyl-*d*-valine: *d*-valine and *l*-valine are obtained by hydrolysing with hydrobromic acid the corresponding formyl derivatives (Fischer, Matsubara and Hilpert, Ber. 1906, 39, 2320).

dl-Valine. In addition to the synthetic methods already described for the preparation of *dl*-valine, it can be obtained by racemising the active acids by heating them with baryta water at 180° (Fischer, Zeitsch. physiol. Chem. 1911, 33, 162).

dl-Valine crystallises in colourless plates from alcohol, has a sweet taste, and melts in a closed tube at 298° (corr.) with decomposition; it is readily soluble in water, 1 part dissolving in 11.7 parts of water at 15°, is almost insoluble in cold alcohol or ether, sparingly so in boiling alcohol (Slimmer, *l.c.*); when oxidised by hydrogen peroxide it yields isobutyraldehyde, isobutyric acid (part of which is further oxidised to acetone and carbon dioxide), ammonia and carbon dioxide; with lead peroxide or sodium hypochlorite as the oxidising agent, isobutyraldehyde is the product (Dakin, J. Biol. Chem. 1908, 4, 63; Langheld, Ber. 1909, 42, 2360). When *dl*-valine undergoes putrefactive decomposition it yields isovaleric acid and a small quantity of butylamine; the residual amino-valeric acid is levorotatory indicating an asymmetric attack by the bacteria (Neuberg and Karczag, Biochem. Zeitsch. 1908, 18, 435).

Salts and derivatives of dl-Valine.—The copper salt $(C_5H_{11}O_2N)_2Cu$, blue crystals soluble in 3644 parts of methyl alcohol at 20°, or in 9230 parts of 96 p.c. ethyl alcohol at 21°, and sparingly soluble in cold water (Ehrlich and Wendel, Biochem. Zeitsch. 1908, 8, 399); the silver salt $C_5H_{11}NO_2Ag$ is crystalline and insoluble in cold water. The hydrochloride

crystalline plates, readily soluble in water or in alcohol, insoluble in ether; the nitrate

is a readily soluble crystalline compound. The ethyl ester $CHMe_2.CH(NH_2)CO_2Et$ has b.p. 63.5°/8 mm. or 174° with decomposition under atmospheric pressure, sp.gr. 0.9617 at 15°/4°; it forms a sparingly soluble crystalline picrate, m.p. 139.5° (corr.), and a soluble hydrogen tartrate which on crystallisation suffers partial resolution into its optically active isomerides (Slimmer, *l.c.*). Of the acyl derivatives of *dl*-valine, the formyl derivative

obtained by heating *dl*-valine with 1½ times its weight of formic acid crystallises in large rhombic plates from water, sinters at 137° and melts at 140°–145° (corr.), is readily soluble in hot water, alcohol or acetone (Fischer, Ber. 1906, 39, 2322); the benzoyl derivative

crystallises in plates, m.p. 132.5° (corr.), is readily soluble in alcohol or ether, sparingly so in water (Slimmer, *l.c.*); the phenylisocyanate derivative $CHMe_2.CH(CO_2H)NH\cdot CO\cdot NHPH$ forms colourless plates, soluble in 130 parts of hot water, m.p. 163.5° (corr.) with decomposition, is readily soluble in hot alcohol, sparingly so in ether, and is converted into phenylisopropylhydantoin

by boiling with hydrochloric acid; this compound crystallises from ether in long needles, m.p. 124°–125° (corr.), and is sparingly soluble in hot water, readily so in alcohol or ether (Slimmer, *l.c.*); the carbamino derivative

crystallises in needles, m.p. 176°, is soluble in 213 parts of water at 20°, and forms crystalline barium, mercury and silver salts (Lippich, Ber. 1908, 41, 2962); the picryl derivative

forms bright yellow needles, sparingly soluble in cold water, and has m.p. 171° (Hirayama, Zeitsch. physiol. Chem. 1909, 59, 290). *dl*-Valinamide $CHMe_2.CH(NH_2)CONH_2$, obtained by the action of liquid ammonia on the ester prolonged over a period of three months, crystallises from benzene in colourless prisms, m.p. 78°–80° (corr.), and yields a β -naphthalenesulphonic derivative $C_{10}H_7SO_3N_2$, m.p. 256°–257° (corr.), a carbothoxy derivative $C_5H_{11}O_2N_2$, m.p. 143–144° (corr.) (Königs and Mylo, Ber. 1908, 41, 4427), and a hydrochloride

crystallising in the monoclinic system, and forming a crystalline platinumchloride

(Lipp, Annalen, 1880, 205, 1). *dl*-Valine anhydride $C_{10}H_{18}O_2N_2$, obtained by heating *dl*-valine, or by heating the ethyl ester under pressure at 180°–190°, forms long colourless needles, m.p. 303° (corr.) (Fischer and Schenkel, Annalen, 1907, 354, 1).

When α -bromoisovalerylglycinamide is

heated at 120° with alcoholic ammonia, it yields a mixture of *valylglycine anhydride* (diketoisopropylpiperazine)

needles from hot water, m.p. 245°, and the *hydrobromide of valylglycinamide*

microscopic needles from alcohol-ether, m.p. 235° (Bergell, *Zeitsch. physiol. Chem.* 1916, 97, 293). α -Amino- β -hydroxyisovaleric acid has been synthesised from ethyl β -dimethylacrylate, it melts with decomposition at 218°; the *methoxyl derivative* $\text{OMe--CHMe}_2\text{--CH(NH}_2\text{)CO}_2\text{H}$ forms colourless lustrous plates, m.p. 250°–260° (decomp.); the naphthalene β -sulphonyl derivative $\text{C}_{10}\text{H}_7\text{O}_2\text{NS}$ forms small colourless needles, m.p. 281° (Schrauth and Geller, *Ber.* 1922, 55, 2783).

Valinol $\text{CHMe}_2\text{--CH(NH}_2\text{)--CH}_2\text{--OH}$, prepared by reducing valine ethyl ester, is a colourless oil with a strong odour, b.p. 181°–186°/720 m.m.; the *hydrochloride*, m.p. 114°, is very hygroscopic.

Dimethylvalinol, prepared by reducing ethyl α -dimethylaminoisovalerate (b.p. 160°), gives with methyl iodide *valinecholine* in the form of its iodide, m.p. 195°; the *aurichloride*

forms yellow leaflets, m.p. 225°, the *platinichloride*, brownish-red prisms, m.p. 210°–211° (Karrer, Gisler, Horlacher, Locher, Mäder and Thomann, *Helv. chim. Acta*, 1922, 5, 469).

d-Valine is most conveniently obtained from the two to three weeks old etiolated seedlings of *Lupinus luteus* and *Lupinus albus*; contamination with leucine, which is very difficult to separate from valine, can be obviated by removing the cotyledons from the young plants before they are dried (Schulze and Winterstein, *Zeitsch. physiol. Chem.* 1902, 35, 312). *d*-Valine is prepared from the synthetic compound by the fractional crystallisation of the brucine salts of the formyl derivative (Fischer, Matsubara and Hilpert, *Ber.* 1906, 39, 2320).

d-Valine crystallises in colourless, shining six-sided plates. It melts in a closed capillary tube at 315° (corr.); when heated in an open tube it sublimes and decomposes partially with formation of the anhydride. It dissolves in 11 parts of water at 16.5°. The taste is first slightly sweet, then bitter (Fischer, Matsubara and Hilpert, *l.c.*). The natural compound obtained from *Lupinus luteus* has $[\alpha]_D^{16} + 28.2^\circ$ in 20 p.c. hydrochloric acid (0.5 gm. in 10 c.c.); from *Lupinus albus* $[\alpha]_D^{16} + 27.9^\circ$ in 20 p.c. hydrochloric acid (0.5012 gm. in 10 c.c.) (Schulze and Winterstein, *Zeitsch. physiol. Chem.* 1902, 35, 299). The synthetic compound prepared by hydrolysing the formyl derivative has $[\alpha]_D^{20} + 23.76^\circ$ in 20 p.c. hydrochloric acid, or $[\alpha]_D^{20} + 6.42^\circ$ in aqueous solution (Fischer, Matsubara and Hilpert, *l.c.*). For the practically quantitative separation of *d*-valine and *d*-alanine by the alternate crystallisation of valine as the free amino acid and of alanine as the phosphomolybdate, v. Levene and Slyke (*J. Biol. Chem.* 1912, 18, 193).

Salts and derivatives of d-valine.—The copper salt $(\text{C}_5\text{H}_{11}\text{O}_2\text{N})_2\text{Cu}$, blue crystalline plates, soluble in 52 parts of methyl alcohol at 18°. The *hydrochloride* $\text{C}_5\text{H}_{11}\text{O}_2\text{N--HCl}$, small prismatic crystals readily soluble in water or alcohol, the *platinichloride* is also readily soluble (Schulze and Barbieri, *J. pr. Chem.* 1883, 27, 337); the *picrolonate* has m.p. 170°–180°, and $[\alpha]_D^{20} + 23.4^\circ$ (Levene and van Slyke, *J. Biol. Chem.* 1912, 12, 127).

Formyl *d*-valine

obtained by the resolution of *dl*-formyl-valine through the brucine salt, forms small prisms, sinters at 150° and melts at 156° (corr.), and has $[\alpha]_D^{20} + 12.8^\circ$ to 13.27° in alcoholic solution; *d*-valine *phenylcarbimide*

forms small microscopic prisms, m.p. 147° (corr.) with decomposition (Fischer, Matsubara and Hilpert, *l.c.*), m.p. 154° (Schulze and Winterstein, *Zeitsch. physiol. Chem.* 1902, 35, 303), and yields the *d*-phenylisopropylhydantoin

on treatment with concentrated hydrochloric acid. This forms colourless thin prisms, m.p. 131°–133° (corr.), and has $[\alpha]_D^{20} - 97.5^\circ$ in alcoholic solution (Fischer, Matsubara and Hilpert, *l.c.*); m.p. 124° (Schulze and Winterstein, *l.c.*); *chloroacetyl-d*-valine

has m.p. 113°–115° (corr.) $[\alpha]_D^{20} + 15.8^\circ$; *glycyl-d*-valine $\text{NH}_2\text{--CH}_2\text{--CO--NH--CHPr}^s\text{--CO}_2\text{H}$ has m.p. 254° (corr.), $[\alpha]_D^{20} - 19.7^\circ$ in aqueous, -10.5° in hydrochloric acid or -6.9° in sodium hydroxide solution; it forms a crystalline *hydrochloride* and a *copper salt*. The *hydrochloride* of the methyl ester $\text{C}_5\text{H}_{11}\text{O}_2\text{N}_2\text{--HCl}$ is converted by methyl alcoholic ammonia into *glycyl-d*-valine-anhydride $\text{CH}_2\text{--}\begin{array}{c} \text{NH--CO} \\ \text{CO--NH} \end{array}\text{--CHPr}^s$, m.p. 266° (corr.), $[\alpha]_D^{20} + 20.8^\circ$ in glacial acetic, $+ 32.7^\circ$ in aqueous or $+ 41^\circ$ in alcoholic solution; *l*-valyl-*d*-valine $\text{C}_5\text{H}_{10}\text{O}_2\text{N}_2\text{, 1}\frac{1}{2}\text{H}_2\text{O}$ becomes anhydrous at 95°/12–15 mm. over phosphoric oxide; has m.p. 308° (corr.), and $[\alpha]_D^{20} - 70.6^\circ$ to -74° ; the *hydrochloride* of the methyl ester yields on treatment with methyl alcoholic ammonia the *trans*-valine-anhydride $\text{CHPr}^s\text{--}\begin{array}{c} \text{NH--CO} \\ \text{CO--NH} \end{array}\text{--CHPr}^s$ prisms, m.p. 316°–318° (corr.), which is optically inactive (Fischer and Scheibler, *Annalen*, 1906, 363, 136).

l-Valine is obtained by the resolution of the racemic formyl derivative through the brucine salt (Fischer, Matsubara and Hilpert, *l.c.*); by the action of ammonia on *d*- α -bromoisovaleric acid (Fischer and Scheibler, *Ber.* 1906, 41, 2891); and by the selective action of yeast on *d*-valine (Ehrlich, *Biochem. Zeitsch.* 1906, 1, 8; 1906, 8, 438).

l-Valine is soluble in 17.1 parts of water at 25°, possesses a markedly sweet taste, and has $[\alpha]_D^{20} - 6.06^\circ$ in 0.24 p.c. aqueous solution.

—29.24° in 20 p.c. hydrochloric acid solution (Fischer, Matsubara and Hilpert, l.c.). A specimen obtained from yeast had $[\alpha]_D^{20}$ —27.62° in a 4.61 p.c. solution of 20 p.c. hydrochloric acid.

1-Formylvaline $\text{CHMe}_2\text{CH}(\text{CO}_2\text{H})\text{NH}\cdot\text{CHO}$ crystallises in small prisms, sinters at 150° and melts at 156° (corr.); it has $[\alpha]_D^{20}$ —12.93° to 13.07° in alcoholic solution, or +16.9° in aqueous solution; 1-valine phenylisocyanate $\text{C}_{15}\text{H}_{18}\text{O}_2\text{N}_2$ has m.p. 147° (corr.) decomp., and $[\alpha]_D^{20}$ —19.02° in absolute alcoholic solution, and yields 1-phenylisopropylhydantoin $\text{C}_{15}\text{H}_{18}\text{O}_2\text{N}_2$ on treatment with hydrochloric acid. It has m.p. 131°–133° (corr.) and $[\alpha]_D^{20}$ +97.22° in absolute alcoholic solution. For iso-valine, α -amino- α -methylbutyric acid, v. Gadamer and Rukop (J. pr. Chem. 1914, [ii.] 90, 405). M. A. W.

VALONIA (Valonée, Fr.; Valonea, Acker-doppen, Orientalische Knopperrn, Ger.). An important tanning material. Is the acorn cup of certain species of oak, usually *Quercus Aegilops* (Linn.), and probably *Q. macrolepis*, *Q. graeca*, *Q. Ungeri*, and *Q. coccifera* (Linn.). The former is most prolific in the highlands of Morea, Roumelia, Greek Archipelago, Asia Minor, and Palestine, whereas the *Q. macrolepis* forms great forests in Greece. These acorn cups have a diameter up to about 1½ ins., and in good condition possess a bright colour.

The fruit ripens in Asia Minor about July or August, and the trees are then shaken, and the material left on the ground to dry; this is subsequently collected into heaps, and allowed to ferment for some weeks, until the acorn contracts and falls from the cup. The acorn, which contains but little tannin, is employed for feeding purposes.

In Greece distinct qualities of valonia are known, the best (*chamada*) collected about April before the fruit is ripe, a second (*rhabdisto*) in September or October, and a third little used inferior variety (*charcola*).

Smyrna valonia may contain 40 p.c., Greek 19–30, and Candia valonia 41 p.c. of tannin matter, which consists of a mixture of a gallo-tannin and an ellagitannin. Valonia is, indeed, an excellent source for the preparation of ellagic acid, because it so readily yields a product easy to purify. Extract of valonia frequently undergoes fermentation with deposition of ellagic acid, and to avoid this the employment of antiseptics is to be recommended.

Valonia is especially suited for the manufacture of sole leather, and together with gambier and other materials for dressing leather, but is little employed for dyeing purposes (cf. Procter, Principles of Leather Manufacture, 259). A. G. P.

VANADINITE. A mineral consisting of lead chloro-vanadate $(\text{PbCl})\text{Pb}_2(\text{VO}_4)_2$, crystallised in the hexagonal system and isomorphous with apatite and pyromorphite (q.v.). The formula requires 19.4 p.c. V_2O_5 , but this is often partly replaced by phosphoric and arsenic oxides; and the variety *endlicheite* forms a passage to the species *milneite* (lead chloro-arsenate). The mineral forms small hexagonal prisms usually terminated simply by the basal plane; at times the crystals are curved and barrel-shaped. Globular, warty, and cauliflower-like masses also

occur. The colour is usually yellowish or brownish, but crystals from Arizona are bright scarlet. Sp.gr. 6.6–7.2. When touched with a drop of nitric acid a yellow coating of vanadic oxide is formed on the crystals; this affords an easy test for recognising the mineral.

Vanadinite is a mineral of secondary origin in the upper portions of lodes of lead ore, and it sometimes occurs in association with gold. It was formerly found in some quantity at Wanlockhead in Dumfriesshire and near Klagenfurt in Carinthia; and now abundantly in several of the mining districts of Arizona and New Mexico. It has been met with at Broken Hill in Northern Rhodesia, and in Morocco. Important localities in Arizona are the Red Cloud mine in Yuma Co., the Mammoth gold mine in Pinal Co., the Globe district in Gila Co., and in Pima Co. and Yavapai Co., &c. In New Mexico at the Sierra de los Caballos near Lake Valley in Sierra Co., Magdalena in Socorro Co., Georgetown in Grant Co., &c. It is also of abundant occurrence at Santa Marta in Badajoz, Spain.

In New Mexico and Arizona, and also in Spain, the mineral is mined as a source of vanadium. The concentrate containing the vanadinite, together with descloizite, is treated in lead-lined vats with dilute sulphuric acid heated by steam, and the vanadium obtained in solution as sulphate, the lead remaining in the insoluble residue. The solution is decanted and evaporated, and the vanadium salt heated to give vanadic oxide. The bulk of this product appears to be used in the manufacture of vanadium-steel, and to a limited extent also as a pigment. Other minerals that have been worked for vanadium are carnotite, descloizite, patronite, and roscoelite (q.v.). L. J. S.

VANADIUM. Sym. V. At.wt. 51.0. This element was discovered by Del Rio (Gilbert's Ann. 1801, 71, 7) in a lead ore, *vanadinite*, from Zimapan in Mexico; the discovery was confirmed by Sefström (Pogg. Ann. 1830, 21, 48), and by Wöhler and Berzelius (ibid. 1831, 22, 1; cf. Collet-Descotils, Ann. Chim. 1805, [i.] 53, 260). Upon the work of Berzelius was based the view that vanadium was allied to chromium and molybdenum and, like them, yielded an acidic trioxide, and this idea was current till Roscoe, in 1867, showed that the substance believed to be the metal in earlier investigations had been either an oxide or a nitride, and that the compounds of vanadium in general showed that the element belonged to the phosphorus group. According to Aston, vanadium is simple with an atomic weight of 51.

Occurrence.—Minerals containing a large proportion of vanadium are rare, but the metal is very widely distributed in small quantities. Vanadium occurs as vanadic acid in *vanadine* with the native copper of Lake Superior, and in *alaite* (Nenadkevitch, Bull. Acad. Sci. St. Petersburg, 1909, 185); as lead vanadate, with lead chloride, in *vanadinite*; as *descloizite*, a basic lead and zinc vanadate; as hydrated vanadate of lead and copper in *mothramite* and *petitite*; as vanadate of copper in *turnite* (Nenadkevitch, l.c.); as lead vanadate containing zinc and manganese in *degenite*, *oreome*, and *eucymite*; as vanadate of lead and arsenic in *endlicheite*; as bismuth vanadate in *pucherite*; as the basic

oxide V_2O_5 in the vanadium muscovite *roscoelite* (Hillebrand, Turner and Clarke, Amer. J. Sci. 1899, [iv.] 7, 451); as vanadate of copper, barium, and calcium in *volborthite*; and as vanadium sulphide V_2S_5 with sulphur, in *patronite* (Hillebrand, *ibid.* 1907, [iv.] 24, 141; Hewett, Eng. & Min. J. 1906, 82, 385; Trans. Amer. Inst. Min. Eng. 1910, 40). See also Vanadium Ores [Monographs on Mineral Resources prepared under the direction of the Imperial Institute], John Murray, London, 1924.

Vanadium is present in magnetites and in most other iron ores (Pope, Chem. Soc. Abstr. 1900, ii. 409), and becomes concentrated in the residues from their treatment, especially by the Thomas-Gilchrist process. It is said to be diffused, with titanium, through all primitive granite rocks (Dieulaufait; Hillebrand, Amer. J. Sci. 1898, 6, 209; 7, 294), and has been found by Deville in *bauxite*, *rutile*, and many other minerals, and by Bechi and others in the ashes of plants and in argillaceous limestones, schists, and sands. Jorissen has found vanadium in the coal of Liège (Bull. Acad. Roy. Belg. 1905, 178). Scacchi has observed its presence in incrustations on the Vesuvian lava of 1631, and Donath has found as much as 0.16 p.c. of vanadic acid in a sample of commercial caustic soda (Dingl. poly. J. 240, 318). It occurs in the sun and has been found in stony meteorites (Hasselberg, Vetensk. Akad. Svenska. 1899, 56, 131).

Extraction.—Ammonium metavanadate was formerly prepared on a commercial scale by the Magnesium Metal Co. at Patricroft near Manchester.

The mineral employed was *mottramite* $(PbCu)_2(VO_4)_2 \cdot 2PbCu(HO)_2$, which occurs in the copper-bearing Keuper beds at Alderley Edge and Mottram St. Andrew's, in Cheshire, as a film on the grains of sandstone. The sand is digested in concentrated hydrochloric acid, and the acid liquid is withdrawn. The solution, with the washings of the residue, is concentrated and evaporated with an excess of ammonium chloride, forming ammonium metavanadate, which, being insoluble in a concentrated solution of ammonium chloride, is precipitated. After being freed from copper and iron by repeated crystallisation, it is gently roasted in a porcelain vessel, with production of vanadium pentoxide. This is suspended in water and subjected to a current of ammonia gas, with formation of ammonium metavanadate, the solution being separated from the silica, phosphates, &c., which are not affected by ammonia, is crystallised until free from phosphates, and gently ignited to produce pure vanadium pentoxide (v. Roscoe, Phil. Trans. 1867, 158, 1).

The chief ores from which vanadium is or may be derived are patronite, carnotite, roscoelite, vanadinite and asphaltite. The chief deposits of vanadium ores, mainly carnotite, in the United States are in South-Eastern Utah and North-Western Colorado, but at present the only vanadium produced from native ore is obtained as a by-product from carnotite worked for its radium content. The principal source of supply at present is in Peru, where deposits occur at *Mina Raja*, about 30 miles to the north-west of the Cerro de Pasco copper mines; here vanadium is found in the coal deposits as a

black mineral resembling slaty coal; it contains about 30 p.c. of free sulphur, with 40 p.c. vanadium sulphide (patronite). After burning out the free sulphur the ore contains from 30 to 52 p.c. of vanadium oxide (V_2O_5). The asphaltite deposits of Peru frequently contain considerable amounts of vanadium, the ash yielding from 25 to 40 p.c. of vanadium oxide.

Vanadium ores are also worked in New Mexico, and carnotite, roscoelite, and vanadinite deposits are found in Colorado, Utah, Nevada, Arizona, and Oklahoma, mainly for the production of ferro-vanadium and vanadium steel. Small quantities of vanadium are also obtained from Argentina (*rafaetite*), Chile (*chileite*), South-West Africa (*mottramite*), and Spain (*vanadinite*).

Two consignments of 25 and 30 tons, respectively, of vanadinite concentrate, averaging 13 p.c. V_2O_5 , from the Kaffir's Krall mine in the Transvaal, constitute the first important shipment of this ore from the Union.

To extract it from vanadinite the mineral is fused with potassium nitrate, alone or mixed with sodium carbonate, the mass is lixiviated, and the solution acidified, or, better, evaporated with ammonium chloride in order to precipitate alumina and silica. From the clear solution barium chloride and ammonia precipitate the barium salts of vanadic, chromic, and molybdic acids, &c., and on treating the product with sulphuric acid, followed by ammonia and water, the vanadium goes into solution as ammonium metavanadate, which is finally precipitated by the addition of ammonium chloride. Vanadic acid may also be separated from mixtures of sodium vanadate and silicate by the addition of more vanadic acid. This precipitates the silica and leaves only fairly pure sodium vanadate in solution (Herrenschmidt, Compt. rend. 1904, 139, 862).

Gin (Proc. Seventh Int. Cong. Appl. Chem. London, 1909) smelts the vanadinite in the electric furnace with 6 p.c. of its weight of carbon, which is sufficient to reduce the base metals, leaving the vanadium in the slag in the form of trioxide. The slag is pulverised and gently heated in a current of air until the trioxide is oxidised to tetroxide; at this stage sodium carbonate and a little nitrate are added to complete the oxidation to vanadic anhydride; the mass is then fused, cooled, pulverised and treated with boiling water, which dissolves the sodium metavanadate together with the phosphate, silicate and aluminate. The cooled solution is treated with carbon dioxide to precipitate silica, and then ammonium carbonate is added and the solution concentrated until ammonium metavanadate is precipitated. This is washed, dried, again washed with water acidified with nitric acid, and calcined to obtain vanadic acid. When electric-furnace treatment is inadmissible, it may be replaced by treatment in a water-jacket furnace, in which case the lead and copper are separated, and the slag is oxidised on the hearth of a reverberatory furnace and mixed with sodium carbonate and nitrate. Or, alternatively, the vanadiferous slag is melted with sodium bisulphate in an iron or steel pan; when the reaction has ceased, the mass is run off on to plates of silicon-steel, pulverised and digested with water in a wooden vessel supplied

with an agitator, steam being introduced during the process. The copper, silver, and arsenic are precipitated from the solution by hydrogen sulphide, ammonia added and the iron and alumina removed. The solution now contains the vanadium in the form of thiovanadate, which is converted into vanadium sulphide by neutralising with dilute acid, and the sulphide is converted into vanadic acid by roasting (J. Soc. Chem. Ind. 1911, 30, 218).

Vanadium can be separated from arsenic or phosphorus by precipitation of vanadic acid from an acidified vanadate solution. A vanadinite concentrate containing 10.24 p.c. V_2O_5 , 0.28 p.c. As, and 0.27 p.c. P, was fused with sodium carbonate, sodium hydroxide, and charcoal. The lead present was reduced to the metallic state and the slag extracted with hot water. After acidifying with sulphuric acid the solution was boiled with live steam for several hours. A 97 p.c. recovery of vanadic acid free from arsenic and phosphorus was obtained (H. A. Doerner, J. Ind. Eng. Chem. 1923, 15, 1014; J. Soc. Chem. Ind. 1923, 42, 1182 A.).

Determination of phosphorus in vanadium ores.—Precipitation of the phosphorus as ammonium phosphomolybdate from a solution containing relatively large quantities of vanadic acid yields an orange-brown precipitate which contains considerable amounts of vanadic acid. The method recommended by Treadwell (Kurzes, Lehrbuch der Analytischen Chemie, 6th ed.), involving previous reduction of vanadic acid to vanadyl sulphate, is also unsatisfactory for determining small quantities of phosphorus in vanadium ores; the precipitate is greenish-yellow, and the results are too high. The most satisfactory of several procedures tested was found to be the following: 10 grms. of finely-divided ore is dissolved in 75 c.c. of hydrochloric acid and 25 c.c. of water, and the solution is oxidised with nitric acid and evaporated with 30 c.c. of sulphuric acid (1:1) until strong, white fumes are evolved. The cold mass is dissolved in 100 c.c. of water, and the sand and lead sulphate are removed by filtration. To the filtrate 50 c.c. of strong nitric acid and 1 grm. of fine tin powder are added, and the mixture is shaken till the latter has dissolved, then set aside overnight in a hot place. The liquid is diluted with 400 c.c. of hot water and filtered. The precipitate is heated in a nickel crucible, and the residue fused with 5 grms. of potassium cyanide, which reduces tin and arsenic to the metallic form. The fused mass is dissolved in water, the solution filtered, and the filtrate boiled with hydrochloric acid to expel all hydrocyanic acid. It is transferred to a graduated flask, treated with potassium ferrocyanide until a spot test gives a brown colour with uranium acetate, when it is diluted to 500 c.c. 450 c.c. is filtered through a dry paper, treated with a solution of an aluminium salt containing about 0.1 grm. of metal, then with a slight excess of ammonia. The precipitate, which contains all the phosphoric acid, is collected, washed free from chloride and ferrocyanide, and dissolved in hydrochloric acid. The solution is evaporated to remove silica, and the filtrate is evaporated with nitric acid to expel chlorine compounds. The phosphoric acid is eventually precipitated as ammonium molybdate and determined in

the usual manner (Kriess, Chem. Zeit. 1923, 47, 177; J. Soc. Chem. Ind. 1923, 314A).

According to Witz and Osmond (Bull. Soc. chim. 1882, [ii.] 38, 49; Compt. rend. 95, 42), the slags produced while working the Thomas-Gilchrist process at the Creusot ironworks contain nearly 1.5 p.c. of vanadium, the quantity of that metal thus concentrated amounting to 60,000 kilos (nearly 59 tons) annually. They recommend the following process for the separation: 1 kilo of the roughly broken slag is treated with a quantity of hydrochloric acid insufficient to attack the whole (about 1 litre of acid of 21°–22°Bé.) without stirring, 3 litres of water being added, and the whole remaining at rest for 2 days. The solution, having a sp.gr. of about 27°Bé. at 36°, is decanted and diluted to 15°Bé., and the silica is removed. The solution contains the vanadium in the hypovanadic condition, and may be used at once for the production of aniline black. If it is desired to produce hypovanadic phosphate, the solution is nearly neutralised and about 250 c.c. of saturated ammonium acetate solution is added. The bluish-grey precipitate produced, containing phosphates of iron, aluminium, and vanadium, is re-dissolved and again treated with ammonium acetate, the precipitate containing about 20 p.c. of vanadium.

If the slag contains less than 1.5 p.c. of vanadium, the hydrochloric acid solution is neutralised by the addition of a further quantity of finely-powdered slag. The solution becomes colourless, and a greyish granular precipitate separates, containing the whole of the vanadium and smaller proportions of the other less soluble phosphates. The precipitate is re-dissolved and re-precipitated as before. For the preparation of ammonium metavanadate, the phosphatic precipitate is roasted at incipient redness, and the ochreous-yellow mass of impure pentoxide is dissolved with the aid of ammonia, boiled until colourless and filtered, the ammonium metavanadate being precipitated by the addition of excess of ammonium chloride. From 4 kilos. of slag containing 1.5 p.c. of vanadium, about 250 grms. of ammonium metavanadate may be produced. It is a colourless transparent salt, or white powder, difficultly soluble in water, insoluble in a concentrated solution of ammonium chloride and in ether. It was formerly used, in conjunction with sodium chlorate, as an oxygen-carrier in the formation of the finest aniline black, only an extremely small quantity of the salt being required for a large amount of aniline.

Später attempted (1896) to employ the ash of an anthracite from Yauli (Peru) containing 28 p.c. of vanadium, but was unsuccessful.

From minerals in which it occurs with uranium, vanadium may be extracted by fusing with potassium hydrogen sulphate, lixiviating the mass and concentrating the solution thus obtained. The solution is reduced with zinc and the vanadium precipitated with ammonia and ammonium carbonate (Zin. Elektrochem. Zeit. 1906, 13, 119).

Haynes states (Mines and Minerals, 1900, 30, 139) that vanadium is extracted from caracoles, in West Colorado, by dissolving out the uranium and vanadium with hot sodium carbonate solution, precipitating the uranium with oxalic soda, and throwing down the vanadium from the mother liquor as calcium vanadate.

also Barker and Schlundt, *J. Soc. Chem. Ind.* 1916, 35, 175.

Fleck and Haldane recommend that the crushed ore be treated with 15-20 p.c. sulphuric acid, the acid liquid neutralised by the addition of fresh ore, and the clear solution fractionally precipitated with limestone, whereby a complex mixture, rich in vanadium, is obtained, from which the element may be extracted by any ordinary method (U.S. Pat. 890752).

It is probable that in future American carnotite ore will for the most part be delivered to the reduction works as concentrates. The most usual process for dealing with these is as follows: They are first boiled in autoclaves with soda ash and water, with stirring, for 6-10 hours. This converts radium and barium salts into the carbonates, 90 p.c. of the uranium present into sodium uranyl carbonate, and 30 p.c. of the vanadium into sodium vanadate. The treated concentrate is settled, decanted, filtered, pressed, and washed free from sulphate. The filtrate and washings contain the uranium and vanadium salts and are evaporated. The cake is acidified with hydrochloric acid and boiled, pressed in wooden filters, and washed. The cake is discarded. The filtrate contains radium and vanadium, and the former is precipitated as radium barium sulphate and removed on vacuum filters. The cake is washed and boiled with soda ash, caustic soda and water, the resulting carbonates are pressed and washed, converted into chlorides, and are then ready for fractional crystallisation. The utmost care must be taken against contamination by sulphates during the stages of this process. The uranium is separated from vanadium by crystallisation as sodium uranyl carbonate, dissolved in water, acidified, and boiled. Any vanadium present is removed by addition of a small quantity of ferrous sulphate, and the uranium precipitated as ammonium uranate. The vanadium in the acid solution from the barium radium sulphate precipitation is precipitated with lime, and the calcium vanadate added to the solution remaining from the sodium uranyl carbonate crystallisation, and the whole boiled with sodium carbonate and a small quantity of manganese dioxide. The solution, containing 95-98 p.c. of the vanadium, is filtered, almost neutralised with sulphuric acid, and freed from phosphate by precipitation with sodium aluminate. The solution is concentrated and vanadic acid precipitated by boiling with a slight excess of sulphuric acid. By this process a minimum yield of 80 p.c. of each product is obtained from carnotite (K. B. Thews and F. J. Heinle, *J. Ind. Eng. Chem.* 1923, 15, 1159-1161; *J. Soc. Chem. Ind.* 1924, 43, 55 B).

Preparation of metallic vanadium.—Roscoe gave two methods for the preparation of the metal; (a) the reduction of vanadium nitride in hydrogen, which never gives a pure product; and (b) the reduction of anhydrous, oxygen-free vanadium chloride in dry hydrogen. For a long time the latter method was the only one known by which the pure metal could be obtained (v. Roscoe and Schorlemmer, *Treatise on Chemistry*), but it can be also prepared by the reduction of vanadium pentoxide with "mischmetall," a mixture of alkaline earth metals extracted from the residues from the manufacture

of thorium (Weiss and Aichel, *Annalen*, 1904, 337, 390). The mixture of mischmetall and pentoxide is placed in a magnesia crucible and fired; the heat of reaction is sufficient to melt the reduced metal, which is afterwards found as a compact mass in the crucible (Muthmann, Weiss and Riedelbauch, *ibid.* 1907, 355, 58).

It was formerly supposed that Goldschmidt's aluminium reduction method would not give pure vanadium from the pentoxide (Koppel and Kaufmann, *Zeitsch. anorg. Chem.* 1905, 45, 352), but under certain conditions Vogel and Tammann have, by this method, obtained a regulus containing 99 p.c. vanadium, with a little silicon and aluminium (*ibid.* 1909, 64, 225).

According to Ruff and Martin (*Zeitsch. angew. Chem.* 1912, 25, 49), vanadium trioxide, melting at about 2000°, gives better results than the pentoxide.

Reduction of the oxide with metallic calcium, according to Muthmann's method, gives a product containing only 91-93 p.c. of vanadium. A purer regulus is obtained by reducing with a mixture of calcium and aluminium (Prandtl and Bleyer, *ibid.* 1909, 64, 217).

Vanadium produced by the reduction of the pentoxide in the electric furnace contains 10-25 p.c. of carbon and consists chiefly of vanadium carbide VC, a silvery-white, highly crystalline and extremely hard substance of sp.gr. 5.405 and m.p. 2705°. A product containing less carbon can be obtained by conducting the operation in an atmosphere of hydrogen (Moissan, *Compt. rend.* 116, 1225; 122, 1297; *Zeitsch. anorg. Chem.* 14, 174).

The pure metal can also be obtained by the electrolysis of a solution of sodium vanadate in hydrochloric acid, using carbon electrodes and a current density of 0.018-0.020 amp. per sq. cm., and maintaining the temperature about 80° (Cowper-Coles, *Eng. and Min. J.* 67, 744; von Bolton, *Zeitsch. Elektrochem.* 1905, 11, 45).

On the small scale it can be obtained by passing a mixture of hydrogen and vanadyl chloride vapour over incandescent platinum wire, when metallic vanadium is deposited as a silver-grey coating, or by passing the chloride over sodium hydride. The reduction of vanadium trichloride with sodium yields a product containing about 96 p.c. of metal and of D_{20} 5.819.

Properties.—Pure vanadium is a silver-white metal, similar in appearance to cast iron, and crystallises in hexagonal rhombohedra, like the other elements of its group. Its hardness is 7.5 on Mohr's scale, and it is as brittle as glass. Its sp.gr. is 5.888 at 18.7 (sp.gr. 5.8 at 15°, 15°, Roscoe), and its specific heat is 0.124 (Maignon and Monnet, *Compt. rend.* 134, 542; Muthmann, Weiss and Riedelbauch, *l.c.*), which, assuming the atomic heat to be 6.4, confirms the atomic weight of 51. Heat of combustion of 1 gm. (to V_2O_5) is 2456 cal.

The melting-point is very high, but the data given by various investigators are not in agreement. Werner von Bolton, using the photometric method of Lammer, found it to be 1680°. Vogel and Tammann give it as 1790°, 1790° (*Zeitsch. anorg. Chem.* 1908, 33, 73); Ruff and Martin 1715°. The melted metal readily dissolves both the trioxide and the pentoxide, and the

mixtures melt at higher temperatures than the metal.

It is stable in moist or dry air at ordinary temperatures, and a polished surface retains its lustre for weeks. It is unacted upon by bromine water, aqueous alkali solutions, hydrochloric acid, or cold sulphuric acid. It is dissolved by hydrofluoric acid or hot sulphuric acid forming green solutions, and is attacked by nitric acid or *aqua regia*. Melted potash or saltpetre rapidly dissolve the metal with formation of an alkali vanadate. Metallic vanadium reduces solutions of mercuric chloride and bromide, cupric chloride and bromide, and ferric chloride to the lower haloid salts, and it precipitates the metal from solutions of auric chloride, silver nitrate, platinum chloride, iridium tetrachloride, &c.

Alloys of vanadium can be prepared in the electric furnace by the reduction of the pentoxide in presence of a second metal or its oxide (Moissan, *Compt. rend.* 1896, 122, 1297). By fusing vanadic acid with aluminium in the necessary proportions, Czako (*Compt. rend.* 1913, 156, 140) has prepared alloys of aluminium and vanadium, and has isolated crystals of Al_3V and Al_4V . The hardness of the alloys increases with the vanadium content up to 60 p.c., after which it diminishes. The chief industrial use of vanadium is in the preparation of special steels, which are largely used for motor-car work; it is introduced into the molten steel as *ferro-vanadium*, an alloy prepared by electric-furnace methods. The addition of 0.1-0.25 p.c. of vanadium to chromium, manganese, or other open-hearth or crucible steels greatly increases the elastic limit and the ultimate tensile stress without reducing the ductility (J. Kent Smith, *J. Soc. Chem. Ind.* 1906, 291; cf. Auchy, *J. Ind. and Eng. Chem.* 1909, 1, 455).

Colloidal solutions of vanadium have been prepared by Svedberg (*Ber.* 1906, 39, 1712). According to Prandtl and Hees (*Zeitsch. anorg. Chem.* 1913, 82, 103) they are best obtained from the solutions of the vanadic esters, especially *tert.* butyl orthovanadate, as the alcohol is easily removed by boiling. Riedel (*Chem. Zentr.* 1914, i. 1738) found that *iso*-amyl orthovanadate $(C_5H_{11})_2VO_4$, b.p. $161^\circ/19$ mm. is the most convenient ester. This is boiled in water until a homogeneous dark red solution is obtained. After removing the amylene hydrate by ether the deep red solution contains about 8 p.c. vanadic acid.

OXIDES OF VANADIUM.

There are five oxides of vanadium, analogous to the oxides of nitrogen—

Vanadium suboxide, V_2O ;

monoxide, hypovanadious oxide, V_2O_3 ;

sesquioxide or trioxide, V_2O_5 ;

dioxide, hypovanadic oxide, $V_2O_4 (VO_2)$;

pentoxide, vanadic anhydride, V_2O_5 .

The first three of these act as basic oxides, forming salts with acids; the last two behave both as weak basic oxides and acid-forming oxides.

Vanadium suboxide V_2O is obtained as a brown powder by the exposure of finely divided

metallic vanadium to the air. No salts of this oxide have been prepared.

Vanadium monoxide V_2O_3 or VO (*vanadyl*) is obtained as a lustrous grey solid by reducing the higher oxides with metallic potassium, or by passing the vapour of vanadyl trichloride with hydrogen over red-hot carbon, or by heating the solid oxychloride $VOCl$ to a red heat in hydrogen. It has sp.gr. 3.64, is brittle and conducts electricity. At a red heat it burns in air to form the trioxide, and it combines directly with chlorine to form the oxytrichloride. This oxide was supposed by Berzelius to be the metal. It is a black amorphous powder D¹⁴ 5-758.

Vanadium monoxide dissolves in acids to form the corresponding salts, which have a blue or violet colour and act as powerful reducing agents. The solution in hydrochloric acid has been suggested as a reagent for the removal of arsenic from hydrochloric acid gas in the process of manufacture, the arsenic being reduced to the free state and remaining suspended in the liquid (D. R. P. 164355).

Vanadium trioxide V_2O_5 , obtained by reducing the pentoxide with hydrogen or carbon at a red heat, is a black powder of sp.gr. 4.7, m.p. 2000° . Heat of formation 302 ± 10 cal. (Ruff and Friedrich). In air it oxidises, slowly at the ordinary temperature, quickly when heated, forming the dioxide V_2O_4 . It is insoluble in most acids.

Vanadium dioxide V_2O_4 or VO_2 is prepared by the oxidation of the trioxide or by the partial reduction of the pentoxide. It is a steel-coloured powder composed of dark indigo-coloured crystals. It dissolves in acids to form solutions of vanadyl salts of a bright blue colour, and in alkalis to form *vanadates* (v.i.). A hydrate, $V_2O_4 \cdot 7H_2O$, or $V_2O_4(OH)_2 \cdot 5H_2O$, is obtained as a greyish-white precipitate by adding sodium carbonate to a solution of a vanadyl salt. At 100° it loses 4 molecules of water, forming $V_2O_4 \cdot 3H_2O$.

Hypovanadic acid (*vanadious acid*) $H_2V_2O_4$ has been prepared by boiling a solution of the dioxide VO_2 in aqueous sulphurous acid. It is a pink crystalline powder (Gain, *Compt. rend.* 1906, 143, 823; see also *ibid.* 1154), and can exist in a green isomeric form (Gain, *ibid.* 1907, 146, 403; *Ann. Chim.* 1908, [viii.] 14, 224).

The salts in which VO_2 is the acidic oxide are derived from the partial anhydrides $H_2V_2O_4$ and $H_2V_2O_5$.

Potassium and sodium vanadates

$K_2V_2O_5 \cdot 4H_2O$ and $Na_2V_2O_5 \cdot 4H_2O$

are prepared by adding excess of caustic alkali to a solution of vanadyl sulphate or chloride (v. Koppel and Goldmann, *Zeitsch. anorg. Chem.* 1903, 36, 281). They form reddish-brown crystalline scales and dissolve in water to dark-brown solutions.

Vanadium pentoxide V_2O_5 is the final product of most commercial processes for the extraction of vanadium from its ores. The pure oxide is best prepared by decomposing vanadyltrichloride with water and fusing the product, or by the decomposition of ammonium metavanadate by heat (Matignon, *Chem. Zeit.* 1904, 29, 206; see also Beard, *Ann. Chim. anal.* 1905, 10, 43). Heat of formation 437 ± 7 cal. (Ruff and

Friedrich, *Zeitsch. anorg. Chem.* 1914, 89, 279).

Vanadium pentoxide forms large rhombic prisms, of a fine ruby-red colour by transmitted light, of sp.gr. 3.35, soluble in about 1000 parts of water with formation of a yellowish, tasteless solution which reddens litmus; this appears to be a colloidal modification of vanadic acid. At 668° (Carnelley) it fuses, forming a red liquid, which recrystallises in needles, with incandescence, on cooling. When the molten acid is poured into water it yields a solution of the colloidal modification (Müller, *Zeitsch. Chem. Ind. Kolloide*, 1911, 8, 302).

When prepared by heating ammonium metavanadate, treating the residue with nitric acid and drying at a gentle heat, it is a yellow, hygroscopic powder which forms hydrates with 1, 2, and 8 molecules of water, and is soluble in water to the extent of 8 parts in 1000. When the oxide is heated at 440°, or fused, two different sparingly soluble modifications are formed (Ditte, *Compt. rend.* 1885, 101, 698).

The properties of colloidal vanadium pentoxide have been studied by Dumaniski (*J. Russ. Phys. Chem. Soc.* 1924, 54 703; *Chem. Soc. Abstr.* 1924, ii, 195).

Vanadium pentoxide is reduced to V_2O_4 by the action of SO_2 , or by evaporation with hydrochloric acid or hydriodic acid in absence of air; to V_2O_3 by magnesium and hydrochloric acid, or by hydrogen in the dry way; to V_2O_2 by zinc and hydrochloric acid (Glasmann, *Ber.* 1905, 38, 600; Chapman, *Analyst*, 1907, 32, 250); or by shaking with mercury in presence of sulphuric or hydrochloric acid:

If a sufficiency of sodium chloride is present the whole of the mercury is precipitated as mercurous chloride, and a blue solution is obtained which may be quantitatively titrated with permanganate:

(McCay and Anderson, *J. Amer. Chem. Soc.* 1922, 44, 1018). The determination of vanadium by reduction with hydrogen peroxide and titration with permanganate has been studied by Hotherhall (*J. Soc. Chem. Ind.* 1924, 43, 270 T, 863 B). Vanadic acid volatilises with hydrochloric acid or to a slight extent when heated with alkaline chlorides.

The pentoxide was formerly used in the preparation of aniline black, and it acts as a carrier of oxygen in many reactions, e.g. the electrolytic oxidation of organic compounds in acid solution (Meister, Lucius and Brüning, *D. B. Z.* 172654), and the oxidation of sugar to oxalic acid or of stannous to stannic chloride (Ludwig, Moeser and Lindenbaum, *J. pr. Chem.* 1897, [ii.] 75, 146; *D. R. P.* 183022).

For the analysis of commercial vanadic acid, see Cheneau (8th Internat. Cong. Appl. Chem. 1913, 1, 123; *J. Soc. Chem. Ind.* 1912, 31, 921).

The Vanadic Acids and their Salts.

Orthovanadic acid H_3VO_4 has not been prepared.

Metavanadic acid HVO_3 may be obtained by boiling copper metavanadate with aqueous sulphurous acid. A mixture of brown and yellow

crystals is first produced, the former being redissolved on continued boiling with excess of sulphurous acid. The remaining yellow crystals consist of metavanadic acid. The acid may also be prepared by addition of a solution of ammonium metavanadate to one of copper sulphate containing excess of ammonium chloride, until a permanent precipitate is produced, and heating for a few hours at 75°. The whole of the vanadium is slowly precipitated, the colour being finer when precipitation is slow (Gerland, *Ber.* 1876, 9, 874). Metavanadic acid forms brilliant golden or orange-coloured scales, which are used as a pigment in place of gold bronze under the name 'vanadium bronze.'

Pyrovanadic acid $H_4V_2O_7$, prepared by the action of nitric acid on an acid vanadate, is a brown precipitate which when air-dried has the above composition (von Hauer, v.i.).

Hexavanadic acid $H_6V_6O_{17}$, formed when a solution of pervanadic acid is allowed to stand, is known only in solution (Düllberg, *Zeitsch. physikal. Chem.* 1903, 45, 170).

The following sodium vanadates are known, and may be taken as typical of the vanadates in general—

- Sodium metavanadate, $NaVO_3$;
- " orthovanadate, Na_2VO_4 ;
- " pyrovanadate, $Na_4V_2O_7$;
- " tetravanadate, $Na_8HV_4O_{17}$;
- " hexavanadate, $Na_6H_2V_6O_{17}$;

(v. also von Hauer, *J. pr. Chem.* 1856, [i.] 69, 385; 1859, 76, 156 and 929; 1860, 80, 324; Carnelley, *Chem. Soc. Trans.* 1873, 323). In solution the metavanadates are most stable, and the orthovanadates least stable, the pyrovanadates being intermediate. This is the reverse of the order of stability of the phosphates. At high temperatures orthovanadates are the most stable salts, being produced, e.g., by fusing alkali carbonates with vanadium pentoxide. The alkali pyrovanadates, prepared by fusing the pentoxide with excess of alkali carbonate and crystallising from water, are soluble, whilst the pyrovanadates of heavy metals are mostly insoluble.

The alkali metavanadates are obtained by boiling a solution of alkali carbonate with the pentoxide, and are colourless salts which give yellowish-red anhydro-salts on treatment with acid. The metavanadates of heavier metals are usually yellow. Pure silver metavanadate is precipitated on addition of silver nitrate to a neutral solution of an alkali vanadate (Browning and Palmer, *Amer. J. Sci.* 1910, 30, 230).

A test which distinguishes between ortho- and meta- vanadates depends on the colour of the copper salts of the acids which are blue-green and light yellow respectively.

A series of double stannates and vanadates of sodium has been described by Prandtl and Rosenthal (*Ber.* 1907, 40, 2125). Mixed alkali tungstates and vanadates by Prandtl and Hecht (*Zeitsch. anorg. Chem.* 1915, 92, 198). Heteropolyvanadates have also been prepared by Rosenheim and Pieck (*Zeitsch. anorg. Chem.* 1916, 98, 223).

By introducing vanadium pentoxide into a boiling aqueous solution of iodic acid, the salt $V_2O_5 \cdot I_2O_5 \cdot 4H_2O$ and $V_2O_5 \cdot 3I_2O_5 \cdot 16H_2O$ may be formed. By using potassium iodide, potassium and ammonium salts of the type

$3R_2O, 3V_2O_5, 3I_2O_5, xH_2O$ are produced. Phosphates give rise to such salts as

and $R_2O, 2V_2O_5, P_2O_5, xH_2O$ (Rosenheim and Yang, *Zeitsch. anorg. Chem.* 1923, 129, 181; *Chem. Soc. Abstr.* 1924, 126, ii, 54).

A number of molybdeno-vanadates such as $4K_2O, 4MoO_3, 3V_2O_5, 7H_2O$ and

have been prepared (Canneri, *Gazz. chim. ital.* 1923, 53, 779; *J. Chem. Soc. Abstr.* 1924, 126, i, 118).

Ammonium metavanadate NH_4VO_3 is the most important salt of vanadic acid. It may be prepared by dissolving vanadium pentoxide in excess of aqueous ammonia and then, by evaporation or by adding alcohol or excess of ammonium chloride, it is thrown out of solution as a white crystalline powder.

Pure ammonium metavanadate (*d* 2.326) is prepared by saturating with ammonia moist vanadium pentoxide and crystallising from a very dilute ammonia solution. One hundred parts of water dissolve 5.18 parts of the salt at 15° and 10.4 parts at 32°; it is only slightly soluble in hot alcohol and in ether. When heated in a vacuum to 135°–210°, the salt yields anhydrous ammonium trivanadate; above 210°, lower oxides of vanadium are formed. On boiling an aqueous solution, soluble ammonium divanadate and the insoluble trivanadate are formed. By the action of 4 p.c. acetic acid on boiling solutions of ammonium metavanadate, the divanadate

is obtained, which on desiccation loses $2H_2O$. Use of 10 p.c. acid gives the trivanadate $3V_2O_5(NH_4)_2O, 2H_2O$ (*d* 2.594), desiccation of which gives an anhydrous red salt (*d* 2.163). The previously described yellow anhydrous trivanadate has *d* 3.029. When the acetic acid is replaced by nitric, hydrochloric, or sulphuric acid, indefinite acid ammonium vanadates are formed, the composition varying with the concentration of the acid added. With a large excess of hydrochloric acid, reduction of the vanadate also takes place (M. Lachatre, *Bull. Soc. chim.* 1924, [iv.] 35, 321; *Chem. Soc. Abstr.* 1924, 126, ii, 409).

A 'vanadium ink' is produced by the addition of gallic acid to a mixture of neutral ammonium metavanadate and gum water. This ink is not destroyed by acids, alkalis, or chlorine but does not appear to be permanent. Soerensen (*J. Soc. Chem. Ind.* 1, 185) recommends the use of a solution of 1 lb. neutral ammonium metavanadate in 10 gals. of water for producing a permanent black dye on leather which has been tanned with nut galls.

A 'drier' for linseed oil may be prepared by heating ammonium metavanadate with rosin or linseed oil. Vanadium is said to be superior to lead in drying power and gives smoother and tougher films than manganese or cobalt. According to Gardner (*Circ.* 149, *Paint Manufacturers Assoc., U.S.*, April, 1923) the time of drying of linseed oil siccatized with vanadium is not markedly different from that of oil siccatized with other known driers.

Perovanadic acid HVO_4 , prepared by adding finely powdered vanadium pentoxide to a solution of hydrogen peroxide acidified with sulphuric acid, forms yellow crystals soluble in water, giving a deep-red solution (Werther, *J. pr. Chem.* 1861, 83, 195; Pissarjewsky, *Zeitsch. physikal. Chem.* 1903, 43, 173). The *potassium salt* KVO_4 forms a yellow microcrystalline precipitate (see also Melikoff and Pissarjewsky, *Zeitsch. anorg. Chem.* 1899, 19, 504; Pissarjewsky, *ibid.* 1903, 32, 341; Melikoff and Kasanezky, *ibid.* 1901, 28, 242; Melikoff and Jelchhaninoff, *Ber.* 1909, 42, 2291; Auger, *Compt. rend.* 1921, 172, 1355).

Vanadioselenious acid $3V_2O_5, 4SeO_3, 4H_2O$ and its salts have been described by Prandl (*Ber.* 1905, 38, 1305).

Vanadium trifluoride $VF_3, 3H_2O$ crystallises in dark-green octahedra from a solution of the trioxide in hydrofluoric acid. Addition of potassium fluoride precipitates the *double potassium salt* $2KF \cdot VF_3 \cdot H_2O$ as a bright green crystalline powder.

Vanadium tetrafluoride VF_4 , a brownish-yellow hygroscopic powder, deliquescent to a blue liquid, is produced by the action of hydrogen fluoride on the tetrachloride.

Vanadyl difluoride VOF_2 is prepared by heating vanadyl dibromide in a current of hydrogen fluoride. It is a yellow powder of sp.gr. 3.396 at 19°.

Vanadyl trifluoride VOF_3 is formed by the action of hydrogen fluoride on vanadyl trichloride. It forms yellowish-white hygroscopic crusts of sp.gr. 2.459, deliquescent to a brownish-yellow solution. Melts at 300° and boils at 490°. May be sublimed in a current of oxygen.

Vanadium pentafluoride VF_5 , obtained as a white sublimate by heating the tetrafluoride in nitrogen. Is readily soluble in water, alcohol, chloroform, acetone and light petroleum. Sp.gr. 2.177; b.p. 111.2°/758 mm (Ruff and Lickfett, *Ber.* 1911, 44, 2539).

Numerous double fluorides have been described (see Petersen, *J. pr. Chem.* 1889, [ii.] 40, 193, 271; Piccini and Giorgi, *Gazz. chim. ital.* 1893, 18, 186; Baker, *ibid.* 1878, 388; Costăchescu, *Ann. Sci. Univ. Jassy*, 1910, 6, 117).

Vanadium tetrachloride VCl_4 is formed by the action of excess of chlorine on the metal or the mononitride. It is prepared by passing the vapour of vanadyl trichloride with chlorine over red-hot sugar charcoal, or by the action of chlorine on the impure metal obtained by Goldschmidt's method (Koppel, Goldmann and Kaufmann, *Zeitsch. anorg. Chem.* 1905, 45, 245), and is separated from admixed oxychloride by fractional distillation. It is readily obtained by the action of chlorine on finely powdered vanadium carbide. It is best prepared by heating the trichloride in a stream of chlorine (Ruff and Lickfett, *Ber.* 1911, 44, 506), or by passing chlorine over heated ferro-vanadium:

(Mertes, *J. Amer. Chem. Soc.* 1913, 35, 671). Heat of formation 165 ± 4 Cal.

It is a deep brown-red, viscous liquid which fumes in air. It boils at 154°, and when heated or exposed to light loses chlorine, forming the trichloride (v.c.). It has sp.gr. 1.8384 at 0° and V.D. 6.66 at 20°. Water decomposes it

with formation of a blue solution of vanadyl chloride. It is soluble in carbon tetrachloride.

The pentachloride does not appear to exist.

Vanadium trichloride VCl_3 is obtained by the decomposition of the tetrachloride, by passing the vapour of the tetrachloride with hydrogen through a red-hot tube, or by heating the trisulphide in chlorine (Halberstadt, Ber. 1882, 15, 1619). It is prepared by passing first the vapour of carbon disulphide and then dry chlorine over heated vanadium pentoxide, or more easily by heating vanadyl trichloride or vanadium tetrachloride with sulphur (Ruff and Lickfett, l.c.). Hydrogen chloride reacts at $300^\circ\text{--}400^\circ$ with vanadium to give the trichloride (Meyer and Backa, Zeitsch. anorg. Chem. 1924, 135, 177). Heat of formation 187 ± 8 Cal.

The trichloride thus obtained forms beautiful purple tabular crystals, resembling chromium chloride. Heated in air, it decomposes yielding the pentoxide. Heated in nitrogen it is decomposed into the tetrachloride and dichloride. When heated in hydrogen it does not volatilise, but is reduced to the dichloride. Its sp.gr. is 3.0, and it is extremely hygroscopic.

The hydrated salt $\text{VCl}_3 \cdot 6\text{H}_2\text{O}$ is obtained by evaporating *in vacuo* a solution of the trioxide in hydrochloric acid (Loeke and Edwards, Amer. Chem. J. 1898, 20, 594), or by reducing electrolytically a solution of the pentoxide in hydrochloric acid and saturating the resulting solution with hydrogen chloride (Piccini and Brizzi, Zeitsch. anorg. Chem. 1899, 19, 394). It is a green crystalline powder, and when heated begins to decompose before all the water has been driven off.

Vanadium dichloride VCl_2 is prepared by reducing the trichloride, by heating to redness a mixture of the trichloride and hydrogen, or by heating the silicide VSi_2 in chlorine (Moissan and Holt, Compt. rend. 1902, 135, 78; Ruff and Lickfett, l.c.). Heat of formation 14 ± 74 Cal.

It forms deliquescent, apple-green hexagonal plates having a micaceous lustre; it dissolves in water to form a solution which bleaches strongly, and is a more powerful reducing agent even than chromous chloride (Piccini and Marino, Zeitsch. anorg. Chem. 1902, 32, 68).

When the solid is heated in hydrogen the pure metal is obtained (Roscoe).

Vanadyl trichloride VOCl_3 (vanadium oxy-trichloride) is prepared (1) by the action of chlorine on the trioxide, some pentoxide being formed according to the equation

(2) by heating the pentoxide to a dull red heat in a stream of chlorine; (3) by heating a mixture of the pentoxide and carbon in a current of chlorine; (4) by passing dry hydrogen chloride over a mixture of vanadium and phosphorus pentoxides at 60° (Ephraim, Zeitsch. anorg. Chem. 1903, 35, 66); (5) by chlorinating a mixture of the pentoxide and sulphur; (6) by heating the trichloride in a current of oxygen. Heat of formation 200 ± 4 Cal.

The product is usually dark-coloured from the presence of the tetrachloride, and is best purified by distillation over metallic sodium in an atmosphere of carbon dioxide.

A solution in acetic acid may be obtained by the action of dry hydrogen chloride on a solution

of the pentoxide in glacial acetic acid (Koppel and Kaufmann, *ibid.* 1905, 45, 352).

Pure vanadyl trichloride is a lemon-yellow mobile liquid; b.p. 127.2° , sp.gr. 1.86534 at $0^\circ/4^\circ$ (Thorpe). In contact with moist air it evolves dense red fumes. Water decomposes it with formation of vanadic and hydrochloric acids, and with a large quantity of water it yields a yellow solution (see Agafonoff, J. Russ. Phys. Chem. Soc. 1903, 35, 649). Heated in a current of ammonia it yields the mononitride. At 70° it combines with ether yielding the compound $\text{VCl}_3(\text{OC}_2\text{H}_5)_2$, crystallising in red needles (Bedson, Chem. Soc. Trans. 1876, i, 309), and it forms a compound with pyridine.

Vanadium may be quantitatively volatilised as the trichloride by heating its compounds in a current of carbon tetrachloride vapour (Jannasch and Harwood, J. pr. Chem. 1909, [ii.] 80, 127).

Vanadyl dichloride VOCl_2 , crystallising in deliquescent green tablets, is formed when the oxytrichloride is heated with zinc at 400° (Thorpe), or with hydrogen at a red heat. The latter method of reduction yields vanadyl monochloride VOCl , a flocculent brown powder, insoluble in water, and divanadyl monochloride $\text{V}_2\text{O}_2\text{Cl}$, a yellow crystalline powder. Double compounds of VOCl_2 , with the hydrochlorides of pyridine and quinoline, have been described (Koppel, Goldmann and Kaufmann, Zeitsch. anorg. Chem. 1905, 45, 345).

Divanadyl tetrachloride $\text{V}_2\text{O}_2\text{Cl}_4 \cdot 5\text{H}_2\text{O}$ is obtained as a brown, amorphous deliquescent mass by the evaporation of a solution of the pentoxide in hot concentrated hydrochloric acid. It dissolves in water to a blue solution which is turned brown by hydrochloric acid or alcohol, possibly owing to the formation of different hydrates (Crow, Chem. Soc. Trans. 1876, ii, 453).

Another oxychloride $\text{V}_2\text{O}_2\text{Cl}_4 \cdot 4\text{H}_2\text{O}$ is obtained by similar methods as a dark-green deliquescent solid (Ditte, Compt. rend. 1886, 102, 1310).

Vanadium tribromide VBr_3 is prepared by the action of dry bromine on the metal on the mononitride, on vanadium carbide V_4C_3 , or a mixture of the trioxide and carbon at a red heat. It is a deliquescent solid which is very unstable and loses bromine even at the ordinary temperature.

The hydrated bromide $\text{VBr}_3 \cdot 6\text{H}_2\text{O}$ is prepared in a similar manner to the corresponding chloride (*q.v.*).

Vanadyl tribromide VOBr_3 , prepared by passing bromine vapour over the heated trioxide, is a dark-red liquid, sp.gr. 2.967 at 0° , b.p. 130° under 100 mm. Heated to 180° it suddenly decomposes into free bromine and vanadyl dibromide VOBr_2 , a brownish-yellow powder. This on further heating yields VOBr , a violet powder, of sp.gr. 4.0, which is eventually decomposed into vanadium tribromide and vanadium trioxide (Ruff and Lickfett, Ber. 1911, 44, 2534).

Vanadium tritelluride (hydrated) $\text{VI}_3 \cdot 6\text{H}_2\text{O}$ is prepared in the same manner as the corresponding bromide.

Divanadyl tetratelluride $\text{V}_2\text{O}_2\text{I}_4 \cdot 8\text{H}_2\text{O}$ is obtained as a dark-coloured deliquescent solid by the action of hydriodic acid on vanadium pentoxide (Ditte, Compt. rend. 1886, 102, 1310).

Vanadium monosulphide VS , obtained by heating the sesquisulphide in hydrogen, is a brown powder soluble in nitric acid.

Vanadium sesquisulphide (*vanadium trisulphide*) V_2S_3 , is prepared by heating the trioxide in a current of hydrogen sulphide or the pentoxide in the vapour of carbon disulphide. It is a greenish-black powder (Kay, Chem. Soc. Trans. 1890, 728; cf. Wedekind and Horst, Ber. 1912, 45, 262).

Vanadium pentasulphide V_2S_5 is obtained as a black powder by heating the trisulphide with sulphur. This sulphide is acidic and gives rise to a series of *thiovanadates*, which are best prepared by passing hydrogen sulphide into cooled solutions of the corresponding vanadates.

Vanadyl sulphite $6\text{VO}_2 \cdot 4\text{SO}_3 \cdot 9\text{H}_2\text{O}$ is obtained as a dark blue crystalline powder by reducing barium vanadate with sulphur dioxide. Gain has described a sulphite $4\text{VO}_2 \cdot 3\text{SO}_3 \cdot 10\text{H}_2\text{O}$, crystallising in silky blue needles (Compt. rend. 1906, 143, 823; see also *ibid.* 1907, 144, 1157).

Vanadous sulphate $\text{VSO}_4 \cdot 7\text{H}_2\text{O}$ is best prepared by acting with sulphur dioxide on a suspension of vanadium pentoxide in sulphuric acid and then reducing the solution electrolytically. On evaporation *in vacuo* the salt is obtained in reddish-violet monoclinic crystals which appear to be isomorphous with ferrous sulphate. The solution of the salt is a powerful reducing agent and bleaches strongly.

Vanadous sulphate forms a series of double salts with the alkali sulphates (see Piccini, Zeitsch. anorg. Chem. 1899, 19, 204; Piccini and Marino, *ibid.* 1902, 32, 55; Marino, *ibid.* 1906, 50, 49; Rutter, *ibid.* 1907, 52, 368; and Zeitsch. Elektrochem. 1906, 12, 230).

Vanadium sesquisulphate $\text{V}_2(\text{SO}_4)_3$, prepared by reducing a solution of vanadium pentoxide in sulphuric acid with magnesium, or by the electrolytic reduction of vanadyl sulphate, forms a green solution from which green crystals of the acid salt $\text{V}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4 \cdot 12\text{H}_2\text{O}$ separate out. By dissolving this salt in water, adding sulphuric acid and heating at 180° in a current of carbon dioxide, the sesquisulphate separates out as a yellow crystalline powder, insoluble in water (Stähler and Wirthwein, Ber. 1905, 38, 3978). Alkali vanadium sulphates of the form $\text{MV}(\text{SO}_4)_2$, have also been prepared (Rosenheim and Mong, Zeitsch. anorg. Chem. 1925, 148, 25; Chem Soc. Abstr. 1925, 128, i, 1411).

Several *vanadium alums* have been prepared.

Vanadyl sulphate $\text{V}_2\text{O}_5(\text{SO}_4)_2$ is prepared (a) in the insoluble form by dissolving the dioxide VO in sulphuric acid and heating the solution at 260° (Gerland, Ber. 1877, 10, 2109; Koppel and Behrendt, Zeitsch. anorg. Chem. 1903, 35, 154); (b) in the soluble form by heating the insoluble form with water at 130° , or by dissolving the dioxide in sulphuric acid, evaporating, and treating the residue with alcohol. Both forms are blue, and by crystallisation of the soluble form under different conditions hydrates with 18, 10, 7, 4, 3, and 2 molecules of water are obtained.

Strongly acid solutions deposit the acid sulphate $(\text{V}_2\text{O}_5)_2\text{H}_2(\text{SO}_4)_2$, crystallising with 5 molecules of water. When heated it gradually loses water, yielding various lower hydrates, and, finally, at 190° , the *anhydrous salt*

which forms microscopic green tetragonal crystals, sparingly soluble in water (Koppel and Behrendt, L.c.; Gain, Compt. rend. 1906, 143, 1154).

Divanadyl trisulphate $(\text{VO})_2(\text{SO}_4)_3$ is obtained in ruby-red octahedra by boiling the pentoxide with excess of sulphuric acid (see Ditte, *ibid.* 1886, 102, 77). Other basic salts, e.g. $(\text{VO}_2)_2\text{O}(\text{SO}_4)_2$ and $\text{VO}(\text{OH})\text{SO}_4$, have been described (see Gerland, Ber. 1878, 11, 98).

Vanadium pyrophosphate $\text{V}_4(\text{P}_2\text{O}_7)_3 \cdot 30\text{H}_2\text{O}$ is formed as a flocculent green precipitate when an alkaline pyrophosphate solution is added to a solution of vanadium ammonium alum (Rosenheim and Triantaphyllides, Ber. 1915, 48, 582).

Vanadium mononitride VN may be obtained by the direct union of its elements or by heating ammonium metavanadate or the pentoxide to whiteness in a current of ammonia. It is a brown powder, oxidised to the blue oxide when heated in air.

Vanadium dinitride VN_2 is a black powder obtained by the action of ammonia on vanadyl trichloride.

Many phosphovanadic and arsenovanadic acids are known, giving rise to numerous derivatives (see Ditte, Compt. rend. 1886, 102, 757; Gibbs, Amer. Chem. J. 1886, 7, 118, 209; Friedheim, Ber. 1890, 23, 1530, 2600; Gain, Compt. rend. 1907, 144, 1271; Mawrow, Zeitsch. Chem. 1907, 55, 147). Blum has described a series of phosphovanadic molybdates (J. Amer. Chem. Soc. 1908, 30, 1858).

Vanadium boride VB is formed by heating a mixture of its constituents in the electric arc. It is a hard metallic looking substance. Stable towards alkalis and acids but readily decomposed by fused alkali hydroxide.

Vanadium carbide VC , obtained by heating the pentoxide with carbon in the electric furnace, forms hard crystals of sp.gr. 5.405; m.p. 3100°Abs .

Vanadium silicides. Two silicides are known: V_2Si , sp.gr. 5.48; and VSi_2 , sp.gr. 4.42. Both are obtained in the electric furnace from the oxide and silicon. They are hard, crystalline substances, having a metallic lustre (Moissan and Holt, Compt. rend. 1902, 135, 78, 493; Meyer and Backs, Chem. Soc. Abstr. 1924, ii, 558).

A vanadium aluminium silicide $\text{V}_2\text{Al}_2\text{Si}_2$, has been described by Manchot and Fischer Annalen, 1907, 357, 129).

For *vanadic esters and other organic vanadium compounds*, see Hall, Chem. Soc. Trans. 1887, 51, 751; Prandtl and Hess, Zeitsch. anorg. Chem. 1913, 82, 103; Barbieri, Atti R. Accad. Lincei, 1914, [v.] 23, ii, 408; Mertens and Fleck, J. Ind. Eng. Chem. 1915, 7, 1037.

Detection and estimation of vanadium.—Vanadium may be detected *qualitatively* by the behaviour of its compounds on oxidation and reduction, yellow or red solutions of vanadates yielding blue solutions of vanadyl salts on reduction with zinc and acid. Addition of ammonium chloride to a solution of a vanadate precipitates white ammonium metavanadate. The most delicate test known for vanadium consists in adding hydrogen peroxide and ether to a solution of a vanadate acidified with sulphuric acid; a yellow or red colour is produced in the aqueous layer (G. Werther, J. pr. Chem.

1903, [L.] 88, 195; Campagne, Chem. Zentr. 1904, [H.] 1167). Vanadium may also be detected spectroscopically (see Purvis, Trans. Camb. Phil. Soc. 1906, 20, 193; Pollok, Sci. Proc. Roy. Dubl. Soc. 1909, 11, 331).

For the arc spectrum of vanadium, see W. F. Meggers (J. Washington Acad. Sci. 1923, 13, 317-325).

Vanadium is usually estimated volumetrically by oxidation methods after other reducible metals have been eliminated. See art. ANALYSIS, and also Hartmann (Zeitsch. anal. Chem. 1925, 66, 16).

For the volumetric estimation of vanadium in steel, see A. T. Etheridge (Analyst, 1923, 48, 588).

Atomic weight.—The atomic weight of vanadium was estimated by Roscoe (Phil. Trans. 1868, 158, 1) to be 51.23; by Prandtl and Bleyer (Zeitsch. anorg. Chem. 1909, 65, 152; 1910, 67, 257) as 51.07; by McAdam (J. Amer. Chem. Soc. 1910, 32, 1603) as 50.96; and by Briscoe and Little (Chem. Soc. Trans. 1914, 105, 1310) as 50.95.

VANADIUM INK v. VANADIUM.

VANADIUM MICA v. ROSCOELITE.

VANILLA is the dried fermented pod of certain orchids, indigenous to Mexico, but also found in Java, Réunion, the Seychelles, Brazil, Peru, on the banks of the Orinoco, Parahyba and other rivers of South America.

The chief cultivated variety is *V. planifolia* (Andr.), which is grown on a considerable scale in Mexico, Réunion, Mauritius, Madagascar, the Seychelles, and in Java. The long fleshy stem of the plant clings by its aerial rootlets to trees, and bears a greenish-white flower. The fruit is a pulpy pod, about 6-12 ins. long and half an inch thick. In Mexico the plant is cultivated by planting cuttings at the feet of trees left in a clearing of the forest; these root in a few weeks and bear in the third year. In Réunion and in the Seychelles the plants are trained on trellis-work supported by trees, and are fertilised by hand. Care has to be taken to gather the pods at the proper time of maturity, as if over-ripe they split in drying, and if under-ripe they are deficient in flavour.

The fruit is usually gathered in the late autumn when full grown, but just before it ripens.

The curing of the fruits consists essentially of a slow process of drying in warm air, using either artificial or solar heat, but the details vary in different countries; thus in Mexico the gathered pods are allowed to lie in heaps until they begin to shrivel, after which they are heated, either by exposure to the sun or in ovens, when they gradually acquire a dark-brown colour. In Réunion and Madagascar the pods are immersed in boiling water for a few seconds, and then exposed to the sun for a few weeks in woollen cloths until they acquire the proper brown colour. As they become dry, they discharge a viscid liquid from the upper end, and are pressed from time to time to promote its flow. They are usually packed for the market in small bundles of fifty or one hundred in each. The yield of vanilla beans in Madagascar and dependencies for the season 1921-22 was 909,000 lbs., and in Réunion and Mauritius 121,000 and 2000 lb., respectively.

It has also been suggested to use calcium

chloride in the drying of the beans (J. Soc. Chem. Ind., 1898, 180).

For literature on the culture and curing of the vanilla beans, v. *ibid.* 1893, 707; *ibid.* 1896, 679; *ibid.* 1900, 847; *ibid.* 1901, 1048; *ibid.* 1906, 1117; *ibid.* 1909, 1002; Fr. Pat. 367285, 1906.

Those who habitually handle vanilla beans are often subjected to a cutaneous affection in the form of an eruption on the hands, face, or neck, which causes intense irritation; this is probably due to the oily juice which exudes from the beans. To avoid the affection, good ventilation of the factories and thorough washing of the hands are recommended (Clavierie, J. Soc. Chem. Ind. 1908, 1082).

Commercial vanilla beans are almost black, 15-20 cm. long and 6-9 mm. thick. They are of a flattened cylindrical shape, tapering towards each end, wrinkled and flexible. The best varieties, chiefly the Mexican, are the largest; they are very dark, glossy, and frost or *givre* (i.e. become covered with white crystals) very quickly. The inferior varieties are shorter, lighter in colour, and do not frost much.

Vanillons are the cured fruits of uncultivated vanilla plants; they are usually of poor quality. The unripe beans are said to contain coniferin and two enzymes, one of which converts coniferin into coniferyl alcohol and glucose, and the other oxidises the former to vanillin (Lecomte, Compt. rend. 1901, 133, 745).

Best Mexican vanilla beans contain 1.60-1.86 p.c. vanillin, Bourbon 1.91-2.90, Java 2.75, German East African 2.16, Ceylon 1.48, Tahiti 1.55-2.02, but the flavour of vanilla does not depend merely on the quantity of vanillin it contains (Busse, Zeitsch. Nahr. Genussm. 1899, 2, 519). The best qualities of vanilla beans contain less actual vanillin than the cheaper varieties.

In addition to vanillin, the beans also contain vanillic acid $C_8H_7(OH)(OCH_3)CO_2H$, resins, fat, sugar, and 4-5 p.c. ash (Winton and Silverman, J. Soc. Chem. Ind. 1902, 1300; U.S. Pat. 931805; *ibid.* 1909, 1062; Gautier and Kling, Ann. Falsif. 1910, 3, 200). Anisyl alcohol and anisaldehyde have also been detected (Walbaum, Chem. Zentr. 1909, ii, 2181).

When the green vanilla pods are exposed to ultra-violet rays, they emit a smell of vanillin, the process being accelerated by a rise in temperature and by previous immersion in dilute manganous chloride (Pouget, Compt. rend. 1911, 152, 1184).

Tincture or essence of vanilla is formed by extracting the ground or cut up vanilla (10 parts) with a mixture of alcohol and water, and mixing the extract with 20 parts of refined sugar, the whole being made up to 100 parts.

The extracts obtained from several varieties of vanilla and tonka beans, using isopropyl alcohol, ether, acetone, and carbon tetrachloride, when compared with that obtained with ethyl alcohol showed that the alcoholic solvents are much superior as regards quality of extract, carbon tetrachloride giving the poorest extract. It is possible, however, that a preliminary extraction with ether or carbon tetrachloride, followed by extraction with a dilute solution of alcohol, may give satisfactory extracts (J. W. Sale, J. Ind. Eng. Chem. 1923, 15, 728-734; J. Soc. Chem. Ind. 1923, 43, 347 A-348 A).

The chief constituent in vanilla extracts is coumarin, either artificial or from tonka beans; good imitation extracts may be obtained from 3 parts of vanilla, and 1 part of tonka beans, but most commercial imitations contain no vanilla, and are made up of artificial vanilla and coumarin and extract of tonka beans, the whole being coloured with caramel (Winton and Silverman, *l.c.*). In the preparation of inferior extracts weak alcohol and alkali are employed; these can be distinguished from good extracts by shaking a few c.c. with 3 volumes of water, when, if no alkali has been employed, a flocculent red precipitate will be formed. With hydrochloric acid a good extract should give only a slight turbidity (Hess, *J. Amer. Chem. Soc.* 1899, 21, 719).

Vanilla in the form of its tincture, is employed for flavouring chocolate and confectionery. It is also largely used in the manufacture of liqueurs and perfumes. See also Vanille, Vanilline, Vanille-Extracten. W. L. Utermark, Amsterdam: Kolonial Instituut, 1922.

VANILLIN (4-hydroxy-3-methoxybenzaldehyde $C_8H_8(OH)(CHO)(OCH_3)$) is contained in vanilla beans (*v. VANILLA*); in *Habenaria nigra* (R. Br.) (Lippmann, *Ber.* 1894, 27, 3409); in dahlia tubers (*ibid.* 1906, 39, 4147); in the woody parts of plants (*ibid.* 1904, 37, 4521); in the fruit and roots of *Avena sativa* [L.] (Rawton, *Compt. rend.* 1897, 125, 797). It also occurs in many other plants, in resins, balsams, and other substances (Campani and Grimaldi, *Bull. Soc. chim.* 1890, [iii.] 3, 458; Weld, Tollens and Lindsey, *Ber.* 1890, 23, 2990; Thomas, *Arch. Pharm.* 1899, 237, 271; Knitt, *ibid.* 256; Itallie, *ibid.* 1901, 239, 506). Vanillin may be obtained from vanilla pods by disintegrating the latter with sand and extracting with ether or a mixture of ether and alcohol (Tiemann and Haarmann, *Ber.* 1876, 9, 1287).

Vanillin may be obtained artificially by oxidising coniferin or coniferyl alcohol with chromic acid; by oxidising eugenol or, better, isoeugenol with air (Fr. Pat. 316526, 1902; Eng. Pat. 4909, 1902; *J. Soc. Chem. Ind.* 1902, 722; *ibid.* 1903, 439). According to A. Lowy and Catherine M. Moore (*Am. Electrochem. Soc. Trans.* 1922, 42, 273), contrary to the claim of D. R. P. 92007 (1897), no appreciable proportion of vanillin could be obtained by the electrolytic oxidation of isoeugenol. The latter is highly susceptible to oxidation to a wide variety of possible products and vanillin itself is readily oxidised electrolytically (*Sci. Abstr.* 1924, 27, 575). In the oxidation of the sodium salts of isoeugenol, or of acetyl isoeugenol in presence of aromatic amino carboxylic acids, extracting acetylvainillin from the products of the reaction, converting this into the bisulphite compound and treating successively with acid and sodium hydroxide (Slevers and Givaudan & Co., Swiss Pat. 89053); with ozone or ozonised air (Trillat, *Compt. rend.* 1901, 133, 822; *Bull. Soc. chim.* 1903, 29, 45; Fr. Pat. 326775, 421784, 1909; U.S. Pat. 829300, 1906; *J. Soc. Chem. Ind.* 1903, 819); with peroxides (Eng. Pat. 11952, 1894; 14923, 1896; *J. Soc. Chem. Ind.* 1895, 806; *ibid.* 1897, 633); or electrolytically (Eng. Pat. 1624, 1895; *ibid.* 1895, 48, 322).

These attempts to oxidise isoeugenol by

ozonised air on a commercial scale have not been uniformly successful, owing to the formation of a resin as a result of the reaction being a very rapid one. In the new process the plant consists of a series of four towers partly filled with splash plates or balls. The first two contain a mixture of isoeugenol and aqueous sodium bisulphite, while the third and fourth are smaller and contain sodium carbonate and hydroxide respectively. Ozonised air is drawn through the towers and the vanillin dissolves in the bisulphite solution as formed. After 8 hours the aqueous layer is run off, the bisulphite compound decomposed with the requisite quantity of sulphuric acid (determined by titration of a test sample), rendered slightly alkaline with sodium carbonate, and extracted with benzene. The crude vanillin recovered from the benzene solution is crystallised three times from water, the last crystallisation being from water completely free from iron. The power required for ozonisation is given as $\frac{1}{2}$ kva. per oz. of vanillin (B. G. Wood, *Met. & Chem. Eng.* 1923, 28, 806; *J. Soc. Chem. Ind.* 1923, 42, 626A).

A 95 p.c. yield and a much purer product is said to be obtained by oxidising eugenol, isoeugenol, coniferin, or coniferyl alcohol, simultaneously with air and ultra violet rays at 50°-60° (D. R. P. 224071; *J. Soc. Chem. Ind.* 1910, 1036).

The conversion of isoeugenol to vanillin by ozonised air has been studied by Briner, Patry, and E. De Luserna (*Helv. Chim. Acta*, 1924, 7, 62), by conducting a current of ozonised air at varying concentrations of ozone (5 p.c. to 19 p.c.) into a solution of isoeugenol in carbon tetrachloride, at temperatures from 15°-150°. The highest oxidation efficiency obtained, in terms of ozone consumed, was 20 p.c. at the lowest temperature. At higher temperatures the efficiency falls off rapidly and the quantity of resinous by-product formed increases (*Chem. Soc. Abstr.* 1924, 126, 1, 290).

Vanillin may also be prepared by dissolving 14.2 kilos protocatechuic aldehyde in concentrated sodium carbonate solution, and mixing it with 12.6 kilos of dimethyl sulphate. The whole is heated on the water-bath, acidified, and extracted with ether. The latter is evaporated, and the vanillin extracted from the residue with chloroform (*J. Soc. Chem. Ind.* 1902, 274; see also *ibid.* 1897, 633; *ibid.* 1894, 1218; *ibid.* 1895, 1061).

Pure vanillin may be synthesised by the following method, the yield being 70-80 p.c. of the theoretical: 1 gm. molecule of a methyl or ethyl ester of mesoxalic acid or of any α -diketonic acid (or of the free acid) is added to a solution of 250 grms. of zinc chloride in 500 grms. of glacial acetic acid. The whole is kept at the ordinary temperature for 15 hours, after which it is heated at 50° for some hours, and then diluted with water and shaken with ether. The ethereal extract is washed with dilute aqueous sodium carbonate, distilled with steam to remove guaiacol (if present) and oxidised with copper chloride or acetate, vanilloylcarboxylic acid being formed. The latter, when heated with an equal weight of dimethyl-p-toluidine at 170°, yields vanillin, which is extracted from the acidified mixture by means of ether (Gayot and Gry, *Compt.*

read. 1909, 140, 928). Vanillin may also be synthesised by treating guaiacol with hydrocyanic acid, hydrochloric acid, and zinc chloride in the presence of infusorial earth (D. R. P. 189037; Chem. Zentr. 1906, i, 73).

A nearly theoretical yield of vanillin sodium hydrogen sulphite is obtained when dry hydrogen is passed through a boiling mixture of vanilloyl chloride-*p*-toluenesulphonic ester (154 pts.), dry xylene (1000 pts.), and palladised barium sulphate (5 p.c., 30 pts.) until evolution of hydrogen chloride ceases (Eng. Pat. 131161).

Vanillin has also been prepared by other methods.

The process of the Ozone Vanillin Co. (U.S. Pat. 829100) consists in passing ozonised air into a mixture of isoeugenol and sodium bisulphite solution of 30°Bé. The vanillin produced unites with the bisulphite from which it is easily separated. The production in the United States in 1919 was 134,700 lbs., valued at \$1,365,900 (Census of Industrial Products). Gattefosse and Morel describe a method of producing vanillin from phenol which consists in nitrating the phenol, separating the ortho- and para-derivatives by steam distillation, methylating the ortho-nitrophenol by dimethyl sulphate in presence of caustic soda to produce *o*-nitroanisole, which is then reduced by zinc powder in presence of calcium chloride to *o*-aminoanisole. This is converted by diazotisation into guaiacol, which by treatment with formaldehyde and hydroxylaminobenzenesulphonic acid yields vanillin.

These reactions may be thus represented:

Literature.—Tiemann, Ber. 1891, 24, 2877; Angier and Boissien, Bull. Soc. chim. 1895, 13, 519; Bouveault, *ibid.* 1898, [iii.] 19, 75; Verley, *ibid.* 1901, [iii.] 25, 48; J. Soc. Chem. Ind. 1899, 558, 740; *ibid.* 1902, 68; *ibid.* 1908, 644; Stolz, Ber. 1904, 37, 4149; Frdl. 1877-87, i, 563-590; 1890-94, iii, 894-900; 1894-97, iv, 1272-1291; 1897-1900, v, 101, 110; 1902-04, vii, 755; 1905-07, viii, 1280, 1281; 1907-10, ix, 162, 1130, 1166.

Vanillin forms white needles having a strong characteristic taste and smell, m.p. 80°-81° b.p. 285° (without decomposition in a stream of carbon dioxide) or 170°/15 mm. It is soluble in 90-100 parts of water at 14°, and in 20 parts at 75°-80°; it is readily soluble in ether, alcohol, and chloroform. Curves of solubility in aqueous alcohol and aqueous glycerol are given by Mange and Ehler (J. Ind. Eng. Chem. 1924, 16, 1256). The aqueous solution is acid, and gives a blue-violet colour with ferric chloride. When treated with ferrous sulphate and bromine water, vanillin is coloured bluish-green, then yellow (Pharm. J. 1897, 58, 187). Vanillin in hydrochloric acid gives characteristic colour reactions with phenols, ketones, and other substances; thus with acetone and its homologues a rose colour is formed, which becomes green on warming (Rosenthaler, Zeitsch. anal.

Chem. 1905, 44, 292). A nitric acid solution of vanillin on standing yields a small quantity of hydrogen cyanide (Jorissen, J. Soc. Chem. Ind. 1910, 1636).

When oxidised with ferric chloride, nitric acid, or with fungus extract, or with gum arabic solution, vanillin forms *dehydrodivanillin*

white needles, m.p. 303°-304° (Tiemann, Ber. 1885, 18, 3493; v. Lerat, Bull. Soc. chim. 1904, [iii.] 31, 270; Bourquelot and Marchadier, *ibid.* 1248; Bentley, *ibid.* 1900, [iii.] 24, 942).

Vanillin may be estimated by converting it into its hydrazone by treatment with a hydrazide (Hann, Zeitsch. Nahr. Genussm. 1900, 3, 531, 657; *ibid.* 1905, 10, 585); or by converting it into its bisulphite derivative, decomposing the latter with sulphuric acid, removing the sulphur dioxide with a stream of carbon dioxide, then extracting the vanillin with ether; the ether is evaporated and the residue weighed (Busse, *ibid.* 1899, 2, 519; Doherty, J. Roy. Soc. N.S.W. 1914, 47, 157). For other methods, see J. Soc. Chem. Ind. 1893, 718; *ibid.* 1903, 514. Or it may be estimated colorimetrically by adding a phosphotungstic phosphormolybdic acid solution to an acid solution of vanillin, and comparing the intensity of the blue colour produced with that formed under like conditions by a standard solution of vanillin. For details, see Folin and Denis, J. Ind. Eng. Chem. 1912, 4, 670. Or 1 c.c. of the vanilla essence is extracted with ether, the extract evaporated over the water-bath, and the aqueous solution filtered and diluted to 50 c.c. in a Nessler glass. Ten drops of freshly prepared bromine water and ten drops of 10 p.c. ferrous sulphate are then added, and the green colour matched against a 0.2 p.c. solution of pure vanillin. Methods for determining vanillin are critically reviewed by Radcliffe and Sharples (Perf. Ess. Oil Rec. 1924, 15, 396, 437; 1925, 16, 20, 51, 87, 156, 197, 271, 353, 387).

A refractometric determination of vanillin in vanilla sugar may be made by shaking 3 grms. of the sugar with 3 c.c. of ether for 1 minute, and allowing to settle. The butyro-refractometer readings of the ether used and that of the ethereal solution of vanillin are then taken. The difference multiplied by 0.4 gives the percentage of vanillin in the sugar. The temperature of the prism should be the same for both readings.

A volumetric method of determining vanillin depends on the formation of a hydro-derivative by the interaction of vanillin and *p*-toluidine dissolved in 80 p.c. alcohol. This compound contains the original hydroxyl group of the vanillin, and is therefore soluble in alkali, giving a yellow solution. A measured excess of standard alkali is added, followed by a comparatively large volume of cold water. The addition of standard acid first neutralises the excess of alkali and then liberates the anhydro-derivative from its sodium salt. The first drop of acid which liberates the derivative produces a yellow turbidity, the free derivative being practically insoluble in the liquid phase. The volume of alkali required for the titration of the vanillin is thus obtained. Accurate results are obtained when benzoic acid is present as an adulterant in quantities up to 10 p.c. but

with higher percentages of acid it is advisable to use a gravimetric method. No sample of first-class vanillin contains more than 1 p.c. of acid (as vanillic acid), though some of the samples had been kept in cardboard containers for 10 years. The gravimetric method suggested comprises the precipitation of vanillin as the semi-carbazone from dilute acetic acid solution. The precipitate is easy to wash and filter and may be dried in a water oven for 6-8 hours, without losing a weighable quantity by volatilisation. The vanillin may be separated from impurities, such as piperonal, by dissolving the semi-carbazone in ammonia solution. Vanillin semi-carbazone, by virtue of its hydroxyl group, forms a soluble ammonium salt, giving a yellow solution, whilst piperonal semi-carbazone is insoluble. Test analyses in which piperonal was added to vanillin gave results agreeing with the actual percentage to within 1 part in 450. The oxidation of samples of purified vanillin exposed to air, moisture, and light was practically negligible. With vanillin in solution, however, oxidation proceeds much more rapidly, while solutions of vanillin in alkali behave similarly to alkaline pyrogallol solution. The following corrected melting-points are given: vanillin semi-carbazone, 232°C.; piperonal semi-carbazone, 218°C.; vanillin-*p*-nitrophenylhydrazones, 148°C. (S. B. Phillips, *Analyst*, 1923, 48, 367-373; *J. Soc. Chem. Ind.* 1923, 42, 948 A).

Oxidising agents, in particular ferric chloride, convert vanillin into *dehydrodivanillin*

m.p. 302°-305°C., and the precipitation of the latter can be observed from aqueous solutions containing as little as 1 in 10,000 of vanillin. 20 c.c. of the solution to be tested is heated in a bath containing a solution of calcium chloride at 130°-140°C., and two fractions of 10 c.c. of distillate are collected. Further quantities of 10 c.c. of water are added to the residue and distilled off, until nine or ten such fractions have been collected. These fractions are tested with ferric chloride, it being easily possible to detect and characterise 0.01 gm. of vanillin in the 20 c.c. of sample taken (*cf.* *Chem. Soc. Abstr.* 1923, ii, 887; H. Herisey and P. Delauney, *J. Pharm. Chim.* 1923, 28, 257-262; *J. Soc. Chem. Ind.* 1923, 42, 1197 A).

For other methods, see Fellenberg, *Chem. Zentr.* 1916, ii, 391; Dox and Plaisance, *Amer. J. Pharm.* 1916, 88, 481; Estes, *J. Ind. Eng. Chem.* 1917, 9, 142.

Vanillin is frequently adulterated with coumarin, acetanilide, and with acetyl isoeugenol (Hess and Prescott, *J. Amer. Chem. Soc.* 1899, 21, 256; see also *J. Soc. Chem. Ind.* 1898, 1076; *ibid.* 1899, 604).

According to Winton and Lott (*ibid.* 1910, 1268) genuine vanillin may be distinguished from imitations by determining the lead number which, for the former, should lie between 0.29 and 0.34.

DERIVATIVES OF VANILLIN.

Vanillin forms salts with zinc, lead, sodium, and magnesium of the type $(C_6H_3O_3)M'$ (Tiemann and Haarmann, *Ber.* 1874, 7, 614).

Bromovanillin $C_6H_3Br(OCH_3)(CHO)(OH)$, m.p. 130°-131°, adonises, yellow leaflets (Tiemann

and Haarmann, *l.c.*); the corresponding *iodo* compound has m.p. 174° (Bentley, *Amer. Chem. J.* 1900, 24, 172).

2-Nitrovanillin has m.p. 137°, 5-nitrovanillin, m.p. 176° (Bentley, *l.c.*; Fiechorn and Sumuleanu, *Ber.* 1899, 32, 3405).

Vanillin forms an *aldoxime*, m.p. 121°-122° (Decker and Klausner, *ibid.* 1904, 37, 520); a *phenylhydrazone*, m.p. 105° (Tiemann and Kees, *ibid.* 1885, 18, 1662); an *azine*, m.p. 174°-176° (Knöpfer, *Monatsh.* 1909, 30, 29); an *acetyl* derivative, m.p. 77° (Fiechorn and Sumuleanu, *l.c.*); a *benzoyl* derivative, m.p. 75° (Wörner, *Ber.* 1896, 29, 143); also a *di-* and *trithio* derivative, in which the oxygen of the aldehyde group is replaced by sulphur, m.p. 129°-130°, 235°-237°, respectively (Manchot and Zahn, *Annalen*, 1905, 345, 320; Wörner, *l.c.*). *Vanillinacetic acid* $CHO \cdot C_6H_3(OMe)O \cdot CH_2 \cdot CO_2H$ has m.p. 188° (Gassmann and Krafft, *Ber.* 1895, 28, 1871).

Vanillin-*p*-phenetidine (*eupyrin*)

is formed by the interaction of vanillin and *p*-phenetidine at 140°; m.p. 97°. It is said to have hypnotic and antineuralgic properties (D. R. P. 91171, 96342; *Frdl.* 1894-97, iv, 1183, 1185).

Benzaldivanillin forms microscopic needles, m.p. 221.5°-222.5° (Rogoff, *Ber.* 1901, 34, 3881; *ibid.* 1902, 35, 1961).

Methyl ether of vanillin (veratraldehyde) $(CH_3O)_2C_6H_3CHO$ may be obtained by the methylation of vanillin, and by other methods. It is best to dissolve 1 mol. of vanillin in less than the equivalent quantity of 10 p.c. methyl sulphate on the water-bath, 1 mol. of potash in solution is then added in drops. When the reaction is over the solution is made slightly alkaline when it separates into two layers. The upper layer is extracted with ether, and on distilling off the latter, the pure aldehyde is obtained (Decker and Koch, *Ber.* 1907, 40, 4794). It has m.p. 47° (Juliusberg, *ibid.* 119), and possesses hypnotic properties. The corresponding *ethyl* derivative $CH_3O \cdot C_6H_3(OC_2H_5)CHO$ has m.p. 64°-65° (Tiemann, *Ber.* 1875, 8, 1120). Homologues of vanillin have also been prepared (*Eng. Pat.* 10112, 1895; *J. Soc. Chem. Ind.* 1895, 595).

o-Vanillin (*m*-methoxysalicylic aldehyde) $(CHO : OH : OMe = 1 : 2 : 3)$ is, in the pure state, a solid which crystallises from water in pale yellow needles, m.p. 45.5°, b.p. 265°-266°. It dyes wool and silk from an acid bath a golden or lighter yellow, but the shades are not fast to soap (Noelting, *Bull. Soc. Ind. Mulhouse*, 1909, 79, 401; *J. Pharm. chim.* 1908, 28, 173).

It gives a *phenyl-hydrazone*, m.p. 130°-131°, and a large number of other derivatives. *Cf.* Perkin and Robinson, *Chem. Soc. Trans.* 1914, 105, 2376; Mosimann and Tambor, *Ber.* 1916, 49, 1261.

The root of a species of *CMorocodon* of Uganda, where it is termed *Murundo*, contains an odorous constituent $C_6H_3O_3 \cdot OMe$, m.p. 41°-42°, b.p. 257°-258°, which forms thin, colourless plates, is isomeric with vanillin, and yields an *oxime*, m.p. 138°, and a *phenyl-hydrazone*, m.p. 137°-138° (Goulding and Pelly, *Chem. Soc. Proc.* 1908, 62).

VANTHOFFITE. The presence of this double salt, $3\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4$, in the abraum-salts at Wilhelmshall near Stassfurt, was detected by plotting on curves the results of several analyses of material from an apparently homogeneous specimen, which was found to consist of a mixture of vanthoffite, loewite, apthitalite, halite, &c. Such intimate intermixtures of minerals of different kinds are really of the nature of rocks, and they must be studied by the methods of petrography; namely, by the examination of thin sections in the polarising microscope, and by separating the individual minerals with the help of heavy liquids (e.g. mixtures of methylene iodide and benzene or tetrabromoethane and toluene). Similar mixtures containing vanthoffite have also been found in the Berlepsch mine at Stassfurt. The mineral has also been observed as nodules embedded, with loewite, in bloedite at Hall in the Tyrol. It is colourless with a vitreous lustre, and a flat-conchoidal fracture; sp.gr. 2.7; H. 3½. The mineral is named after J. H. van't Hoff, who, when its occurrence in the salt deposits was discovered, succeeded in preparing it artificially. When crystals of bloedite ($\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 4\text{H}_2\text{O}$) are heated in contact with their mother-liquid to above 70° they are transformed first into loewite ($\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 2\text{H}_2\text{O}$) and then into the anhydrous salt $3\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4$. L. J. S.

VAPOUR DENSITY v. SPECIFIC GRAVITY.

VAREC. *Kelp v. IODINE.*

VARIOLARIN v. LICHENS.

VARIOLARIN. One of the many minerals consisting of hydrated aluminum phosphate, here with the formula $\text{AlPO}_4 \cdot 2\text{H}_2\text{O}$. It forms concretionary and compact nodular masses, sometimes with a minutely crystallised (orthorhombic) surface. The colour is bright apple-green (due to chromium); sp.gr. 2.5-2.6; H. 4-5. It was first found in 1837 in Saxon Voigland (the ancient Variscia), and within recent years has been mined in considerable quantities (3½ tons in 1909, and 2½ tons in 1910) at several places in Utah and Nevada. It is used as a gem-stone, taking the place of green turquoise (D. B. Sterrett, Min. Res. U.S. Geol. Survey, Annual Reports for 1910 and earlier).

L. J. S.

VARNISH (Syn. *Vernis*, Fr.; *Lac*, *Firniss*, Ger.). A varnish may be described as a homogeneous fluid, which, when applied by any suitable means in a thin layer over the surface of any object, dries either by the evaporation of the volatile solvent, or by the combined evaporation of the volatile solvent and the oxidation of the component oils and resins to a more or less impervious elastic film of varying degrees of hardness and of generally good weather-resisting properties.

Varnishes, in the drying of which heat is applied in a well-ventilated compartment to expel the solvent and to complete the oxidation so that the film is uniform like glass, are termed stoving varnishes. The simplest form of varnish is the spirit varnish, which is merely a solution of a more or less elastic solid in a volatile solvent. Spirit varnishes dry the most rapidly, but are liable to be brittle and especially to crack and peel off unless plasticised by the addition of suitable soluble elastic substances. Oil varnishes are, to a large extent,

free from this defect; the drying oils, which they contain, binding and softening the resin, and although they take longer to dry, they are generally more lustrous and durable. When varnish is used as the vehicle or medium for the application of a pigment or a pitch to an object, an enamel is produced. Such enamels dry with a gloss, and save labour by combining painting and varnishing in one operation. The solvents employed in making the various varnishes are chiefly turpentine, naphtha and petroleum spirit, kerosene and white spirit, methylated spirit and, recently, higher aliphatic alcohols, e.g. isopropyl, butyl and amyl alcohols. Linseed oil is the drying oil in most general use, but tung oil (China wood oil) is coming more into demand. Walnut and poppy oils are artists' mediums.

The solids, i.e. resins, &c., mostly employed in oil varnish making are: 1. Copal, including Kauri, Manila and Congo; 2. Rosin, including its glyceryl ester; 3. Asphaltum, including the various pitches. Recently synthetic resins have been tried in the form of coumarons resins and phenol formaldehyde resins incorporated with rosin (Albertols). The resins are solid bodies, generally more or less coloured, amorphous usually with a vitreous lustre, which melt as a rule at comparatively low temperatures often with decomposition. They are insoluble in water, but partially or wholly soluble in a number of solvents, e.g. alcohol, ether, acetone, carbon tetrachloride, benzene, light petroleum, turpentine, &c. In practice the varnish maker is more concerned with the properties of the varnish film than of the original resin, and although, generally speaking, the hardest resin gives the hardest film, the properties of the film are greatly affected by the other ingredients of the varnish and the skill with which they are incorporated.

Resins.—The resins have been classified into hard, medium and soft. Among the hard resins appear Zanzibar and Amber. The medium resins include Kauri, West African and Gold Coast copals. Among the soft resins are Manila (East Indian) and South American resins. Among the spirit varnish resins shellac, dammar, sandarac are hard resins, whereas mastic and rosin are medium, and elemi, oleo-resin turpentine and Burgundy pitch are soft. The solubility of a resin may be said to be in inverse proportion to its hardness. The hard resins and semi-hard resins are but very slightly soluble in their original condition at the ordinary temperature, but they are easily dissolved by turpentine, linseed oil, and other solvents, by previously heating them in such a manner as to cause them to lose by destructive distillation 10-25 p.c. or more of their weight of a resinous oil according to the resin dealt with. This partial destructive distillation of the harder resins is necessary before they will dissolve in oil or other solvents. The temperature to which the resins must be heated before they become soluble, is higher in the case of the hard resins than of the soft resins.

Oil Varnishes.—The first process in preparing an oil varnish is selection of the gum; the pieces are sorted out by hand and graded according to their colour and general soundness, and as the gum gives the hardening properties to the varnish and is the most expensive constituent, great

case is encountered in the solution. The selected gum is heated or 'run' whereby depolymerisation occurs, and then caused to unite with the oil. The gum is heated in a pot of copper, or of iron with a copper bottom, or of aluminium over a rapid fire, until it is perfectly liquid at about 290°-300°C.; a hood or lid is placed over the pot, which is connected to large flues in which the varnish 'fumes' are condensed. The drying oil, specially chosen for varnish making and clarified, is heated and added cautiously at the right moment to the 'run' gum, the whole being kept well stirred, and the heating continued until the mixture is perfectly clear. The driers are added in several ways, either in the form of a lead and manganese soap dissolved in oil or as solid lead and manganese compounds, and the mixture boiled with stirring until the driers are incorporated. The pot is then removed from the fire, and when sufficiently cooled, turpentine or white spirit is added gradually, stirring all the while until the whole is thoroughly mixed. Much inflammable vapour is evolved during these operations, and it is necessary that the varnish house should be so constructed that the vapours do not come in contact with fire.

After the addition of the thinners the varnish is strained into a tank, and allowed to stand until clear for use. The time required for this varies, and as all varnishes improve by age, the longer they are tanked the better. In some cases the driers, consisting of litharge and dry white copperas (cryst. ZnSO_4), are churned at the ordinary temperature with the varnish and the excess of undissolved solids is allowed to settle in tanks. Old varnishes produce surfaces of much greater lustre than new ones. The good qualities of a varnish largely depend on the efficient mixing of the gum and oil; if these are thoroughly incorporated the varnish will be free from spots and blemishes on its surface, while, if well boiled, a varnish is said to flow more freely and to dry more rapidly. Excessive boiling, however, causes the varnish to stouten and thus to require more thinners to bring it to a working consistency, and the resulting fluid, being poorer in its non-volatile constituents, yields a thinner and less lustrous coat. No strict rule on this point can be given, as some oils and gums stouten more rapidly than others, and the final result has to be manipulated according to circumstances.

The drying of oil varnishes varies considerably according to composition, and within certain limits to the proportion of metallic driers present as well as to the objects to which they have to be applied; thus a gold size may dry in a few minutes, while body or coach varnishes require 12-24 hours, and even then should be allowed 2 or 3 days to harden.

Of recent years many attempts have been made to prepare oil varnishes without previous fusion of the gum. Only one has led to successful results, viz. that in which naphthalene under pressure is employed. By this process, which was patented by Terence, the copals are dissolved in naphthalene by heating under pressure to 250°-300°C.; linseed oil or other drying oil is added to the solution and the naphthalene is distilled off. The varnishes obtained by this process are satisfactory and of

good hardness. The objections to the antecolore processes are the capital outlay and the length of time taken in rendering the gum soluble. Other special solvents for copals have been proposed, e.g. linseed oil acids, amyl alcohol, terpineol, &c., but they have met with no success. The effect of the solvent materials on the finished product is deleterious, unless they can be completely removed, which is not feasible. The weight of the gum 'run' in one operation has been steadily on the increase, and nowadays the old charge of $\frac{1}{2}$ cwt. is increased to over 1 cwt. and the whole operation can be performed with complete safety, if proper precautions are taken.

The number of varieties of oil varnishes is large; as many as 200 may be listed, each having its own special use. There is no general classification, although long and short oil varnishes, based on the proportion of resin to oil, is the most acceptable. The most important classes are, coachbuilders' varnishes, including those for carriages, motor cars and railway work; boat, marine and spar varnishes; decorators' varnishes for inside and outside work. Other classes include furniture varnishes, clear and black stoving varnishes and black japans containing pitches. Coachbuilders' varnishes (body and carriage varnishes) must give films which are dust dry within 12 hours and do not crack nor show 'bloom'; moreover, they will retain their lustre for several years, if washed from time to time and occasionally polished with wax. Undercoating varnishes, harder than finishing varnishes, must be sufficiently dry in 10-15 hours to admit of being lightly rubbed down previous to the application of an elastic finishing coat. A film of a blooming varnish shows after a time an opacity which may become permanent. Such surfaces have been found to be strongly polar. Blooming is not confined to oil varnish films. The general formulae of coachbuilders' varnishes may be summarised as follows:

	Resin	Oil	Thinners
Finishing body varnish	60 lbs.	15 gals.	15 gals.
Elastic coach varnish	60 "	12 "	12 "
Hard elastic varnish	60 "	10 "	12 "
Quick hard drying varnish	60 "	6 "	12 "

Undercoating varnishes show bloom when not covered by an elastic finish. Boat varnishes should give a water-resisting film and should not become opaque on immersion in water; these, as well as seaplane varnishes, generally contain China wood oil. Whilst a film of linseed oil never attains a degree of hardness to withstand abrasion, China wood oil gives a harder and more weather-resisting coating. Owing to the rapid gelatinisation of wood oil on heating, copals are largely replaced by rosin and rosin glyceride. Decorators' varnishes for inside and outside work differ slightly in the proportions of gum and oil; the inside varnishes must have good flow, be free from bloom, but great weather-resisting power is not required; for outside work, varnishes on the lines of the carriage varieties are employed. The undercoating varnishes are termed *putting or rubbing*

varnishes, drying rapidly so that in 12 hours they may be rubbed down to a flat surface upon which the finishing variety may be applied. The proportions of gum to oil may be 1:1.25. They are liable to bloom and not durable to weathering unless protected by an elastic finishing coat. Other varieties of decorators' varnishes include: church oak, drying with a hard film, not softening appreciably up to 40°C., suitable for church seats; floor varnish, softer than church oak, with a gum and oil proportion of 1:1.4 or 1:1.67; front door varnish, which must combine elasticity with hardness and lustre; furniture varnish containing rosin: oil=1:1.10, in which rosin is often introduced, and thin coats are applied, rubbing down between each coat until the requisite brilliance is obtained.

Black Japans and Bituminous Varnishes occupy a special position, since they have for their characteristic ingredients a bitumen or asphalt. Both gum resin and oil may or may not be present, as the asphaltic substances differ far more widely in their hardness and elasticity than the various gum resins, and their properties can be modified with greater facility. The most important bituminous varnish in the higher branches of the decorative craft is known as black japan. The term "japan," as applied to substances which promote the drying of a paint film, denotes generally liquids which dry to a hard film possessing considerable coherence. Japan driers give a harder film than the oleo-driers, which are elastic and of a drying-oil character, whilst japan driers are of the nature of a resin varnish containing resin, or rosin with lead and manganese. The specific purpose of black japan is in the production of a brownish-black ground of special translucence or depth, thus differing from pigmented preparations (black enamels), which appear to reflect their depth of colour from the surface only. The main use of black japan in the coach-building trade is for panel work. The varnish is obtained by amalgamating specially treated oil of great drying power with suitable bitumens, in the same manner as described in the manufacture of copal varnish. Black japan itself rarely possesses great elasticity or weather resistance, so that it requires a coating of a suitable finishing varnish. The art of the varnish maker consists in the preparation of a mixing of great degree of depth and intensity of colour without employing so high a proportion of bitumen that the solubility of the latter in the ensuing coat takes place, a condition manifesting itself by the appearance on the finished work of a greenish fluorescence. It is difficult to give a general formula for these coatings, as the quality depends on the selection of the materials. The proportions may be roughly stated as equal quantities of hard resin, asphaltum or petroleum pitch, and boiled oil with turpentine, and white spirit thinners.

Air-drying Black Enamels are made on a similar plan to the coachmakers' black japans, but consist of materials which are not so carefully selected, e.g. asphaltum, rosin, boiled oil, and petroleum thinners. Some contain only pitch, boiled oil, and turpentine, and are known as *Rosowink* blacks, for which the following formula may be considered as fairly represen-

tative: 45 lb. pitch, 6 galls. boiled oil, and 6 lb. litharge, boiled until stringy and then cooled and thinned with 25 galls. turpentine or petroleum. It is evident that the varieties of blacks will be large in number and will have special names according to their requirements. They may be bright or dead; e.g. Berlin black for grates and fenders, in which the introduction of a black pigment such as carbon black produces a matt appearance. Coach and motor builders require a quick black for iron work, drying in about an hour, a black petrol-resisting varnish of brilliant lustre, drying and hardening quickly, and a dead black metal priming, capable of standing great heat, for the exteriors of cylinders of motor cars.

Black Stoving Enamels are of great variety, and a similar classification holds, as in the case of resin oil varnishes as to elasticity, body or viscosity, and temperature of stoving. One-coating, under-coating and finishing, brushing, dipping and spraying modifications are in use.

The marked difference between clear varnishes and black stoving enamels lies in the presence of bitumen. The remaining components are drying oils with their attendant driers and thinners, chiefly kerosene, since the temperature of stoving is higher than that of resin-oil varnishes, viz. 150°-177°C. Some black stoving enamels contain no resin or rosin, but generally a certain proportion is present; but it is difficult to identify the resins in the presence of a mixture of bitumens, especially if stearine pitches have been used. Flow and surface are important properties. The finishing coat must have a high lustre and hardness, and should show no runs or rivelling at the edges under the conditions of application, dipping, brushing, or spraying. The production of high-quality coatings demands careful selection of the components and of the proportions in the mixings. If an under-coating be used it must be adherent to the surface and be rust preventative, providing also a grip for the finishing coat. The under-coatings possess small elasticity, great hardness, good hiding power, but no lustre. They may contain a pigment such as carbon black instead of bitumen, whose function is to leave a dull uniform surface for the finishing coat. The composition and mode of preparation is variable. Among the many published formulae a mixing containing asphaltum, resin, and boiled linseed oil in the proportions of 10; 2.5; 50, with petroleum or turpentine may be considered as fairly representative. The proportions will depend on the requirements and on the temperature of stoving. British Specifications for oil, black and shellac varnishes used in the trade have been issued by the British Engineering Standards Association.

Such black stoving enamels, largely used on ironwork, have great weather-resisting power, but recently cellulose air-drying black enamels have been put forward. It is impossible in the space available to consider adequately the great variety of decorative and protective coatings, as well as their advantages and defects.

For further details reference may be made to R. S. Mornell's *Varnishes and their Components*, 1923; H. M. Langton, *Enamels and*

Pichon, 1923; N. Hoston, Volatile Solvents and Thinners, 1926; T. H. Barry, A. A. Drummond and R. S. Morrell, Resins, Natural and Synthetic, 1926; The Analysis of Pigments, Paints and Varnishes, J. J. Fox and T. H. Bowles, 1926.

Spirit Varnishes.—The manufacture of spirit varnishes is much less complicated than that of the oil preparations, the former being simply solutions of one or more resins in various solvents. On the evaporation of the solvent a coating of varnish is obtained, consisting practically of the unchanged resins. The resins employed for this purpose are chiefly shellac, sandarac, soluble manila, dammar, acaroid, elemi, benzoin, mastic and rosin. The solution of the resins is affected either cold or hot, as circumstances require, heat presenting the advantages of rapid solution and clearing, while the palest varnishes are obtained by the cold process. To facilitate solution the gum should be kept continually agitated, thus preventing the particles of gum from forming a mass. It will be readily seen that the larger the surface of the gum exposed to the solvent the quicker will be the solution. A revolving churn is used, and the rotation keeps the particles in motion and prevents them from caking together. When the gum is all dissolved the varnishes are set aside to settle, and are ready for use almost immediately. They dry very rapidly and are, generally speaking, harder and more brittle than oil varnishes, and as their drying is merely dependent on the evaporation of the solvent the addition of driers is not required. Within recent years many forms of artificial or synthetic resins have come into use. They may be broadly classified into (1) condensation resins—e.g. the formaldehyde-phenolic resins; (2) polymerisation resins—e.g. the coumarone resins, which are obtained by the treatment of certain distillates from coal tar naphtha. Condensation resins are such as are made by preliminary interaction of at least two chemical substances, generally involving elimination of water. Resinification may be completed by a polymerising action.

Formaldehyde phenolic resins.—The most important condensation resin is made from formaldehyde and phenolic compounds. Bakelite is the typical example. Amongst other trade products of similar character are—in America, Redmanol, Condensite, Amberite, Phenoform, Sibolite, Nuloid, Amberdeen, Abalac, etc.; in France, Melusite, Cerite; in Great Britain, Elo, Bakelaque. There is a marked difference in the properties of the formaldehyde phenolic resins compared with the natural resins. The natural resins can be melted, but not 'run,' and cooled, without great change in their solubility or fusibility, but the phenol synthetic resins on heating may, under certain conditions, pass more or less rapidly into solid infusible resins, charring at 300°C.; moreover, the resin becomes insoluble in all ordinary solvents, and has acquired a remarkable increase in strength. It is this marked change in solubility that has made Bakelite products so valuable as a shellac substitute. The formaldehyde phenolic resins are of two distinct types. One type has the same characters analogous to

those form the class of shellac substitutes (called Novolak by Bakeland). They are analogous to shellac in their solubility relationships; they are soluble in alcohol and insoluble in hydrocarbons. The second type of resin is that in which the resin is soluble and fusible only in an intermediate stage and becomes insoluble and infusible on heat treatment, being finally in the *resite* condition, passing through the intermediate *resitol* stage. Bakelite, Elo, and Bakelaque are examples of this latter type. Bakeland terms these latter resins *resinoids*, as they do not possess all the properties common to the natural resins.

For details as to preparation and further application reference must be made to Carleton Ellis, Synthetic Resins and their Plastics, 1923, and to the Chemistry of Natural and Synthetic Resins by Barry, Drummond and Morrell, 1926.

The chemical changes occurring during the manufacture of these substances are not yet understood, although considerable advance has been made during the last few years. The varieties of resin produced is dependent on the amounts of formaldehyde and phenol used and whether the catalyst is acidic or basic in character. Bakeland (J. Ind. Eng. Chem. 1909, 1, 159) uses ammonia as catalyst. An acid catalyst will tend to produce a soluble resin, whereas an alkali favours an insoluble resin. The greatest development of these resins has been in the direction of moulding and insulating compounds.

Formaldehyde-urea Resins.—Condensation products of formaldehyde with urea and thiourea have been used to give viscous products which may be gelatinised in several hours. The reaction takes place in two stages, a condensation phase followed by a polymerisation phase. The solid resins obtained are transparent, colourless, stable, taking a high polish, and may be used as substitutes for glass; Polloplas and the Beetle Products Company resins are examples. In Pollak's Schellian solutions the resin is maintained in water solution by alkali salts of weak acids, e.g. sodium acetate or a borax solution of shellac.

Coumarone Resins are obtained from the fraction of solvent naphtha 150°–200°C., and are polymerised as regards certain of their constituents by sulphuric acid to yield 25–40 p.c. of resin. These resins are not usually soluble in alcohol, and benzene, toluene, solvent naphtha, and turpentine are the best solvents. They are miscible with drying oils. The differences in the technical coumarone resins depend on the variable proportions of indene and coumarone present. The following is a formula for a coumarone oil varnish: China wood oil containing 15 p.c. of linseed oil is incorporated with the resin in the proportion of 5–40 galls. per 100 lbs. resin. The driers used are cobalt or manganese linoleates, and the thinner is heavy refined coal-tar naphtha, b.p. above 160°C. Typical varnish mixtures containing coumarone are described by King, Bayard and Rhodes, (J. Ind. Eng. Chem. 1920, 12, 649) and R. S. Morrell (Varnishes and their Components, 1923).

Cellulose Ester Varnishes.—Only two of these are of any importance in the

industry, viz. the nitrate and the acetate, formed by combination of cellulose with nitric acid and acetic acid respectively. These substances are soluble in certain mixtures of organic liquids, which have a comparatively high rate of evaporation, and when the solutions are spread on solid surfaces they rapidly become dry, leaving the cellulose ester in the form of a continuous film. By making certain additions to the original solutions, the hardness and adhesiveness of the films may be modified. Owing to the rapidity with which the solutions dry, they may be applied at ordinary temperatures, although a warm room is advantageous. As a rule a coating is dry under an hour. All organic protective coatings consist of highly polymerised structures. The degree to which the original cellulose is depolymerised or degraded in structure before and during the manufacture of the ester determines to a considerable extent the properties of the resulting varnish.

Nitrocellulose Varnishes.—The cellulose ester varnishes may be either transparent or opaque. The transparent varnishes may be coloured in practically any tint so as to give a coloured transparent lacquer coating. The opaque varnishes containing pigments may also be obtained in any colour, and are usually termed enamels. It is customary to include all solutions of cellulose esters used for protective or decorative coatings under the general term of cellulose varnishes. They may be applied by brush, but better results are obtained by dipping or by use of an air spray. Under proper conditions the solutions dry with a high polish, and the films resist water, petrol, soap, turpentine, weak acids and weak alkalis.

Cellulose nitrate lacquers.—The common metal lacquer usually contains not more than 5 p.c. of cellulose nitrate, in a mixture of solvents, and serves to delay the tarnishing of metal, not acting as a finishing material. In order to increase the solid content it was necessary to produce cellulose nitrate, which, when dissolved in suitable solvents, gave a solution of low viscosity. The addition of natural resins was found to impart adhesion and rubbing properties in varying degrees according to the resin employed and the amount used. The constituents of finishing lacquers may be: cellulose nitrate of low viscosity, resins to make the film glossy and hard, solvents which control the rate of drying, degree of gloss and viscosity of the lacquer, and plasticides to remain in the film after the solvents have evaporated and so to give it elasticity. Scrap celluloid as a substitute for cellulose nitrate has many drawbacks, and its use is not to be recommended. The resins are either of the soft or medium hard varieties. Butyl alcohol, ethyl, butyl and amyl acetates, ethyl lactate and amyl formate may be used as solvents. D. B. Keyes classifies the solvents into three groups: (1) low boiling solvents, reducing the viscosity of the lacquers and permitting a high rate of evaporation; (2) medium boiling, giving the lacquers the property of flow; (3) high boiling, acting as a wetting solvent, preventing the precipitation of nitrocellulose or the resin.

The lacquers are best applied by spraying, but good results may be brushed on. In

the order of application of the cellulose coatings careful consideration of their elasticity must be taken, so as to prevent subsequent cracking of the film. Pigmented lacquers and enamels have been used for many years as protective coatings for bathroom fittings, cycle and motor lamps and furniture. The following proportions of cellulose nitrate, resin and plasticide have been found satisfactory for interior lacquer enamels: cellulose nitrate 12 parts; resins 6 parts; plasticide 2 parts. This ratio will give a hard and elastic film provided too much pigment is not added. For further details reference may be made to F. Sproston, *Cellulose Ester Varnishes*, 1925.

Cellulose acetate varnishes.—Solutions of cellulose acetate in a mixture of high and low b.p. solvents are used for tanning and weather-proofing linen fabric composing the wing surfaces of aeroplanes. A typical three-coat formula would be cellulose acetate 8.5 parts, acetone 50, alcohol 24, benzene 24, benzyl alcohol 2 and triphenyl phosphate 1.5. For durability the dopes must be specially pigmented and generally require a protective coating of a seaplano oil varnish.

Natural varnishes or lacquers.—Japanese lacquer is the milky juice exuding from the trunk of *Rhus vernicifera* (Tsi-chou, varnish tree). The tapping of the tree resembles that of *pinus* for turpentine oleoresin. The raw varnish, which is frequently adulterated with tung and perilla oils, is known in Japan as *Ki-urushi*. The peculiarity of the varnish is that it hardens only in a moist atmosphere and remains in a tacky condition to sunlight and heat. It is the most durable varnish known and resists the action of air and water excellently. It is stated to be the best protective coating for aeroplane propellers. The application of the lacquer is said to be dangerous to western workers owing to the peculiar poisonous properties of the *urushiol* in the resin. The resin has been investigated by Japanese chemists, who have synthesised hydrourushiol, the reduction product of the active principle of Japan lac. A concise account of Chinese and Japanese manufacture will be found in the Bulletin of the Imperial Institute, 1910, 8, 32; and in Stewart Dick's *Arts and Crafts of Old Japan*, 1908.

R. S. M.

VARVICITE. *Hydrated manganese ore*
 $\text{MnO}_2 \cdot \text{Mn}_2\text{O}_3 \cdot \text{H}_2\text{O}$ (Rammelsberg), or

(Phillips) (v. MANGANESE).

VASOTONIN. Trade name given to a combination of yohimbine and urethane which produces a fall of blood pressure, and appears to have considerable therapeutic value (*China. Soc. Abstr.* 1910, ii, 725).

VAT DYES. The term 'vat dye' is applied to those dyestuffs which, like indigo, are insoluble in water, dilute acids, and alkalis, but which, on being treated with suitable reducing agents, yield leuco compounds which are soluble in the hydroxides of the alkalis or of the alkaline earths, and in dyeing are taken up as such by textile fibres. By subsequent exposure to the air the leuco compound is oxidised and

and in the fibre, with the re-formation of the original colouring matter. The characteristic fastness of the colours thus produced is, in a large measure, due to the insolubility of the dyestuff.

Indigo (*g.v.*), which was formerly the only known vat dye, is by far the most important of this series of colouring matters, and has been used in dyeing from time immemorial. A blue, dyed with it on cotton, is still referred to as a 'vatted blue,' whilst in the woollen industry the term 'wooded blue' means a blue which is dyed either wholly or in part with indigo.

In preparing or 'setting' the indigo vat, various methods are employed in practice to bring about the reduction of the indigotin. This is effected either by purely chemical or by bacteriological means, but in either case the product of the reaction is the same, viz. indigo white, $C_{16}H_{11}N_2O_2$, or graphically,

which dissolves in caustic soda with the formation of either the mono- or di-sodium salt ($C_{16}H_{11}N_2O_2Na$ or $C_{16}H_{10}N_2O_2Na_2$), according to the amount of caustic soda present in the bath. It has been shown that indirubin and thioindigo red also require 2H for reduction, and by analogy it is presumed that the other indigoid dyestuffs behave similarly. In aqueous solution, the mono-sodium salt of indigo white has been shown to be an electrolyte, though it is not so strongly ionised as sodium chloride (Knecht and Batey, *J. Soc. Dyers*, 1910, 171).

The so-called chemical vats are distinguished, according to the reducing agent employed, as the copperas, the zinc, and the hydrosulphite vats. They are used in cotton dyeing, but the hydrosulphite vat also finds a limited application in wool dyeing. In the setting of any indigo vat, it is essential that the indigo should be in a finely divided state. The 20 p.c. artificial indigo paste contains the colouring matter in a sufficiently finely divided condition for the purpose, but the natural product must be ground, before use, to an impalpable powder.

The copperas vat depends upon the reducing action of ferrous hydroxide, and is made up of indigo, copperas and slaked lime. The lime reacting with the copperas forms ferrous hydroxide:

which in turn reduces the indigotin to indigo white:

which then dissolves in the excess of lime present to form the soluble calcium salt. In the copperas vat, there is always a large amount of sediment, and to prevent this coming into con-

tact with the goods during dyeing, deeper vessels are required than with the other chemical vats. At the present time, the copperas vat is not largely used in this country, the main reasons being that its use involves a considerable loss in indigo, and the sediment in the vat is very bulky. On the other hand, the blues obtained in the copperas vat are faster than those obtained in the zinc or hydrosulphite vats.

In the zinc vat, zinc powder is the reducing agent. For satisfactory working, this should contain not less than 80 p.c. of metallic zinc. The vat is set with indigo, zinc powder and lime (or caustic soda). The reduction may be regarded as taking place as follows:

although, according to Binz (*Chem. Ind.* 11, 1902), it is probable that combination of the indigotin with the alkali takes place first, with the formation of a compound

which then reacts with the zinc, forming the same products as shown in the above equation.

This vat is the one which is most largely used in cotton dyeing.

The hydrosulphite vat depends upon the reduction of the indigotin by sodium hydrosulphite, which is usually prepared by stirring zinc dust into commercial sodium bisulphite, in the proportion of a pound of the former to a gallon of the solution; and after allowing to stand for some time, adding to the solution an excess of milk of lime. The so-called 'stock vat' or concentrated vat is made by dissolving the indigo in this muddy liquid. (A product of this kind, containing about 3 p.c. of indigotin, was formerly sold under the name of 'reduced indigo.') This stock vat serves either for making up or for replenishing the dye vat proper. The reduction by means of sodium hydrosulphite may be regarded as taking place according to the following equation:

By employing artificial indigo paste, caustic soda, and the solid commercial sodium hydrosulphite, which is now placed on the market in an almost pure condition and at a reasonable price, it is possible to obtain a vat practically free from sediment.

The dyeing of cotton in the indigo vat is in itself a comparatively simple operation, although the management of the vats requires careful supervision and considerable practical experience. In hank dyeing, the wetted-out hanks are immersed in the vat and turned by hand under the surface of the liquid until thoroughly impregnated with the vat liquor, after which they are withdrawn and wrung, the liquor being returned to the vat. The hanks are then exposed freely to the air, in order to allow of the oxidation of the indigo white to indigotin. By repeating this operation several times, the shade becomes successively darker, and its depth will therefore depend upon the number of 'dips' in

one and the same or in different vats. Although it is possible to obtain a dark shade by a single dip in a strong vat, this is not practised, because it would result in a large proportion of the indigo being loosely fixed and much of it would be lost in washing off; besides, the resulting blue would 'rub off' very badly. The oxidation of the indigo white taken up by the fibre from the vat is usually regarded as taking place in the following manner:—

though under chosen conditions it has been shown by Herzog and Manchot that auto-oxidation may take place, resulting in the formation of equal molecular proportions of indigotin and hydrogen peroxide (Annalen, 316, 318). This interesting observation may account, according to Crowther, for the presence of isatin in the hydrosulphite vat (J. Soc. Dyers and Col. 1911, 146). It is further evident that the dyed cotton material removes a considerable amount of alkali from the vat. Where lime is used in the vat in place of caustic soda, an accumulation of calcium carbonate on the fibre occurs through air exposure, and the goods therefore soured, after dyeing, in dilute sulphuric acid. In the dyeing of cotton warps and of piece goods, the material is guided through the vat by means of submerged rollers, so that it passes many times up and down between the time of entering and leaving; excess of liquor is expressed at the point of exit by means of a pair of squeezing rollers. In case it is desired to give the pieces two or more 'dips' in the same vat, they are stitched together, end to end, so as to form a continuous band, and, after leaving the vat, are passed up and down over a series of loosely running wooden rollers (which are usually placed immediately above the vat in order to economise space) for a sufficient length of time to allow of the oxidation of the indigo white before they re-enter the vat.

The reason why indigo white should be taken up from its aqueous solution by the cotton fibre is imperfectly understood. It has been suggested that it is a case of mutual precipitation between colloids, but as it has been definitely shown (see above) that indigo white lacks some of the most essential properties of a colloid, this theory cannot hold good. In any case, the affinity of indigo white for cotton is but slight, as, when once taken up, it can be completely removed by continued washing with cold, air-free water, whereas a boiling solution of dilute caustic soda removes it from the fibre almost instantaneously. The affinity of indigo white for cotton appears to be similar in character to that of tannic acid for this fibre (Knecht and Nair, *ibid.* 1912, 28).

If the cotton to be dyed in indigo or other vat dyes has been previously mercerised, darker shades are obtained than on untreated cotton. The same applies with regard to indigo and certain indigoid dyestuffs if the cotton has been previously dyed manganese bronze or has been steeped for some time in strong nitric acid (see *Manganisung*). In the latter case, the increase in depth is due in a greater measure to alight nitration of this fibre than to the mercerising effect of the acid.

Indigo dyed on cotton is sometimes associated with other colours. Thus, if a light shade of indigo is 'topped' or subsequently dyed chrome yellow, pleasing and very fast shades of green result. The old-fashioned 'fast black' was obtained by a combination of a heavy shade of indigo and catechu brown. The dyeing of a black of this description was practised by the Incas of Peru prior to the Spanish invasion.

Indigo dyed on cotton is usually regarded as fast to washing and to light. Strictly speaking, however, these qualities are only relative, for by repeated washing in soap or continued exposure to light, the colour (especially in light shades) gradually fades. But in fading it always retains the characteristic colour of indigo and does not change, as is the case with most other blues, to an unsightly grey or drab. It is noteworthy that the fastness of indigo to light may be considerably enhanced by treating the dyed fabric for a few minutes in a boiling dilute solution of copper sulphate.

In Egypt, Persia, India, China, Japan, and other Eastern countries, where dyeing is still almost entirely a household industry, fermentation vats are generally used for cotton dyeing. Such vats are occasionally used in this country for the dyeing of goods for certain markets. The fermentation vat imparts a certain peculiar smell to the goods dyed in it, and unless they possess this smell, the natives in some markets will not accept them as indigo-dyed. A product known as indigo essence, consisting of a mixture of the methyl ethers of α -naphthol and β -naphthol, is put on the market for the purpose of imitating this smell on material dyed blue with dyes other than indigo.

The dyeing of wool with indigo differs from the dyeing of cotton in that whereas cotton is invariably dyed cold, the temperature of the vat for wool dyeing must be maintained at from 50° to 55°. Another point of difference is that in the case of wool, the time of immersion in the vat has to be much longer than in the case of cotton.

For wool dyeing, especially where fermentation vats are used, natural indigo is generally preferred to the artificial product.

Only one of the vats generally used in cotton dyeing can be used with advantage in wool dyeing, viz. the hydrosulphite vat. This is set with indigo, sodium hydrosulphite and ammonia. Although the cost of working this vat is greater, as far as materials are concerned, than that of the fermentation vats, this is more than compensated by its greater output. It is, however, only suitable for light to medium shades of blue.

The fermentation vats, of which a considerable variety are in use in different countries and sometimes in one and the same country, might appear at first sight to depend for their action upon different principles. But it is probable that in all cases the action depends upon a bacterial decomposition (butyric acid fermentation) of the carbohydrates, in which hydrogen is generated. Various substances containing carbohydrates, such as bran, flour, sugar, treacle or dates, are used along with lime, potash, or soda for the purpose. The setting and management of fermentation vats require considerable skill and experience, and in all large works these matters are under the sole

control of the 'blue dyer,' upon whose intelligence and efficiency the prosperity of the works largely depends.

The fermentation vat mostly used in this country is the so-called *woad vat*, which is set in a vessel having a capacity of from 1600 to 3000 gals. with indigo, woad, bran, madder and lime, the temperature being maintained at 60°. The fermentation will have set, as a rule, in from three to five days, and the vat will then be ready for use. Once set, a woad vat simply requires replenishing, from time to time, with the necessary additions of indigo, lime, and bran, and may remain in use continuously for many years. It should be explained that in this vat the woad, which in former times (before the introduction of indigo from India) was the only indigo-bearing dyestuff used in this country and on the Continent, now acts solely by virtue of the bacteria which it contains, for in commercial woad there is, at the present day, no indigotin, the whole of the colouring matter having been destroyed by bacterial action.

Dyed on wool, indigo resists the action of light better than when dyed on cotton.

The disulphonic acid of indigotin, which is obtained by heating the dyestuff to about 100° with excess of concentrated sulphuric acid, is known commercially as indigo extract or, in the form of its sodium salt, as indigo carmine. It dyes wool 'at the boil' from a bath containing sulphuric acid and Glauber salt a much brighter shade of blue than that obtained in the vat, but the colour is neither fast to light nor to soap, and goods so dyed cannot be classed as being dyed with indigo.

Silk is seldom dyed in the indigo vat, although fast and pleasing shades can be obtained in this way.

Indigo in printing.—In textile printing, notably in calico printing, indigo may be regarded as the most important individual dyestuff in use at the present time. This is partly due to the favour which it finds with the public as being pleasing to the eye and relatively fast, and partly to the variety of styles to which it lends itself in this branch of textile colouring. Effects are obtained with indigo in printing in three entirely different ways, viz. by direct printing, by the discharge process, and by the resist process.

In direct printing, the indigo is not printed on to the fabric in the reduced condition (a process which would obviously suggest itself at once to any one acquainted with its properties and its application in dyeing) owing to practical difficulties which this mode of application entails. The process in actual use is the so-called *glucose process*, in which glucose and caustic soda serve as the reducing agent. The pieces are first prepared by padding in a solution of glucose and are then dried. The finely ground indigo is made up with strong caustic soda thickened with maize starch and British gum. This is printed on to the prepared calico and the goods are run through a rapid ager containing air-free moist steam, the time required for this treatment being about half a minute. During the steaming, the indigo is reduced to indigo white which dissolves in the caustic soda and penetrates into the fibres. By subsequent exposure to air, the indigo white slowly oxidises

back to indigo blue. The operations of preparing in glucose and drying may be dispensed with by adding to the printing colour a suitable reducing agent such as the formaldehyde compound of sodium sulphonylate (hydrosulphite NaF.). This has no action on indigo in the cold, but reduces it on steaming for two to three minutes. The goods are then exposed to the air as in the glucose process.

Indigo may also be produced on the fibre in printing (or in dyeing) by means of *indigoool*, a product discovered by Messrs. Sunder and Bader, and recently introduced by Messrs. Durand and Huguenin. The new product is a comparatively stable compound of indigo white, soluble in water and in caustic soda. The printed or padded pieces are run through a weak bath of nitrite of soda and acid, when the indigo instantly develops on the fibre. The blues obtained in this way are faster to rubbing than those obtained in other ways.

In the discharge process, which lends itself to a greater variety of effects, the whole piece is first dyed to the required depth of blue in the vat and the colour is then removed locally either by destroying it by means of oxidising agents or by reducing it to the leuco compound and removing this by means of boiling dilute alkali. The former process, which is the one chiefly employed, consists in printing sodium chromate, suitably thickened, on to the blue fabric. After printing, the goods are run through a warm solution of sulphuric and oxalic acids, when in consequence of the liberation of chromic acid, the indigo is oxidised to isatin and this is removed in the subsequent washing, a white pattern on a blue ground resulting. For coloured discharges, the chromate is mixed with albumen and a suitable pigment, such as vermilion or chrome yellow, and the goods are run, after being printed, through the mixture of acids at a temperature high enough to coagulate the albumen. The fixation of the pigment and the destruction of the indigo thus take place simultaneously. The process is capable of many modifications. Thus, in order to obtain a bright scarlet on a blue ground, the indigo-dyed fabric is padded first with an alkaline solution of β -naphthol, dried and printed with a colour containing diazotised *p*-nitraniline and sodium dichromate. The *p*-nitraniline red thus formed resists the action of the chromic acid formed when the pieces are run through acid and a bright red on a blue ground results.

Indigo may also be discharged by printing on sodium nitrate and running the goods through warm sulphuric acid of 100°Tw. (Freiberger's process).

In the reduction discharge process, the pieces are printed with the formaldehyde compound of sodium sulphonylate with or without the addition of a catalyst such as anthraquinone. They are then steamed in the rapid ager to reduce the indigo and immediately run through a boiling bath of caustic soda, soda ash, or sodium silicate. The indigo white is thus completely removed and there is no tendering of the discharged places, as is invariably the case when the chromate discharge is used.

In the resist process, the fabric is first printed with a mechanical or with a 'chemical resist' and is then dyed in the vat. Wherever the resist

has been printed no colour is fixed, and a white pattern on a blue ground results. In the East, and also to some extent in European print works, wax is used as the resist. After dyeing it is removed by soap and alkali. When the goods are handled (as in dyeing) after the wax has been printed on, the latter cracks in places so that in the dyeing some of the reduced indigo liquor penetrates through the fissures, with the result that fine blue veins are afterwards seen in the pattern. This defect is characteristic of all true Battick work, which the modern printers are at pains to imitate.

The 'chemical resist' mostly used at the present time is a very thick colour containing copper sulphate, lead nitrate, and China clay, usually thickened with flour and British gum and with or without the addition of such mechanical resists as tallow or rosin. As with the wax resist, the dyeing is best conducted in the zinc vat. By increasing the amount of lead nitrate in this resist so as to exceed its equivalent in copper sulphate, and running the goods after dyeing through sodium dichromate, lead chromate is formed in the resisted parts and a yellow pattern on a blue ground results.

VAT DYES OTHER THAN INDIGO.

Although it has long been known that indirubin (an isomeride of indigotin which occurs in almost all natural indigos) can be dyed in the same manner as indigo, it has never found any technical application, partly on account of the shade it yields being undesirable and partly for other reasons. The tetrabromo (5:7:5':7') derivative, obtained by brominating the artificially prepared dyestuff in nitrobenzene solution is, however, a useful vat dye, and comes into the market under the designation *Ciba Heliotrope B. Indophenol*, which was discovered in 1882 by Koechlin and Witt, is also a vat dye, and although it was a commercial article in the '90's it was never much used, mainly because it produced loose colours, and it is now entirely obsolete.

The enormous development in the vat colour industry that has taken place during the last few years may be traced, on the one hand, to the discovery of indanthrene blue by Bohn in 1901, and on the other hand to the synthesis of thioindigo red by Friedländer in 1905. At the present time there are well over one hundred individual dyestuffs which may be strictly classed as vat dyes, without taking into account the large number of sulphide colours (*q.v.*) which, in a sense, might also be classed as vat dyes. It would obviously be out of place to embody the whole of our present knowledge of the vat dyes in this work, as that would require an amount of space which would not be commensurate with the general interest attaching to the subject. In the following, it will therefore be understood that the examples given are only typical of the various classes. For further information on the subject of vat dyes, see Engi, *Chem. Zeit.* 1908, 1178; Bohn, *Ber.* 1910, 987; Staebli, *Chem. Zeit.* 1910, 731 *et seq.*; Friedländer, *ibid.* 1911, 640; Masera, *Färber-Zeit.* 1911, 336; Grandmougin and Battagay, *Ela. Text. Bl.* 1910; Maffoch, *J. Soc. Dyers*, 1910, 26; Ermen, *ibid.* 1910, 56 and 236; E. de Barry Barnett,

ibid. 1913, 183; L. E. Vlies, *ibid.* 1914, 22; Truttwin, *Enzyklopädie der Küpenfarbstoffe*, 1920; J. F. Thorpe and C. K. Ingold, *Vat Colours*, 1923; The 'Colour Index' of the Society of Dyers and Colourists, edited by F. M. Rowe, 1924; Knecht, Rawson and Loewenthal, *A Manual of Dyeing*; Knecht and Fothergill, *The Principles and Practice of Textile Printing*, 1924.

These vat dyes may be classed under two headings, viz. as (a) indigoid dyestuffs, and (b) anthraquinonoid dyestuffs. The former come into the market under various trade names such as indigos of various brands, the Durindope colours (British Dyestuffs Corporation), Alizaranthrene colours (British Alizarine Co.), and the Ciba colours (Soc. of Chem. Ind., Basel), while the latter are represented by the Duranthrene colours (British Dyestuffs Corporation), the Caledon colours (Solway Dyes Co.), and the Cibanon colours (Soc. of Chem. Ind., Basel) *V. INDIGOID DYESTUFFS*, Vol. III, p. 620.

The bromo derivatives of indigotin are brought into the market under different designations, such as indigo pure R.B.N., ciba blue, indigo K2B, and generally yield, in dyeing and in printing, either redder or greener shades of blue than indigo itself, according to the amount of bromine which they contain. Thus *indigo R* is 5 bromoindigo, *ciba blue 2B* is 5:7:5':7'-tetrabromoindigo, and *indigo KG* consists mainly of 4:5:7:4':5':7'-hexabromoindigo. There is no object to be gained in substituting more than five hydrogen atoms in the indigo molecule, as the leuco compounds of the more highly halogenated derivatives are so sparingly soluble as to preclude their practical application. The 6:6'-dibromoindigo synthesised by Friedländer, and shown by him to be identical with the *Tyrian purple* of the ancients, is not a commercial article. It is interesting to note that the 6:6'-dibromoindigo dyes an amethyst shade (Tyrian purple) whereas the isomeric 5:5'-dibromoindigo (*indigo RB*) dyes blue. The position occupied by the halogen atoms in the molecule is of importance in other instances. Thus the entrance of the halogen atoms in the para-position with reference to the nitrogen atoms causes but little alteration in the colour, although the shades are brighter than those from indigo itself. If the halogen atoms occupy the para-position to the CO groups, the dyes obtained are redder in shade than indigo.

Of homologues of indigo, the 7:7'-dimethylindigo (*methyl indigo B*), and the 5:5'-dimethylindigo (*methyl indigo R*) are the most important commercial representatives. The former dyes cotton a greener and the latter a redder shade of blue than indigo itself.

Thioindigo red B or thionaphthene indigo

was discovered in 1905 by Friedländer and is obtained by fusing o-carboxyphenylthioglycollic acid with caustic potash to form thioindoxyl, which is then oxidised to the dyestuff. This dye results from the action of dichloroethylene on thioacetylic acid, followed by treatment with sulphuric chlorohydrin. The discovery of this product marked the beginning of

a new era in the history of organic colouring matters, for it opened up a new field and has resulted in the introduction of a large number of new and valuable vat dyes. Like artificial indigo and most other commercial vat dyes, thioindigo red B comes into the market in the form of a 20 p.c. paste. The pure colouring matter is readily obtained from the dried paste by crystallisation from benzene or toluene in well-defined dark red crystals. Its solution in benzene is red and shows a characteristic intense yellow fluorescence. In concentrated sulphuric acid it dissolves with a bluish-green colour; but on pouring the solution into water, the original dyestuff separates. By warming with fuming sulphuric acid, it is sulphonated and the soluble sulphonic acid thus obtained dyes wool from an acid bath a full bluish shade of red. Unlike indigo, thioindigo red is not affected by oxidising agents, remaining unaffected by chromic acid, alkaline ferrocyanide and bleaching powder; whilst, on the other hand, it is more readily reduced than indigo. It has been shown that the reduction of thioindigo red to its leuco compound is analogous to that of indigo, two atoms of hydrogen or their equivalent being required for one molecular weight of the dyestuff (Knecht, J. Soc. Dyers, 1906, 156). Like indigo white, the leuco compound dissolves readily in caustic alkalis, forming a yellow vat from which it is taken up by the cotton fibre, the red reappearing on exposure to the air.

Of derivatives of thioindigo red, the following may be mentioned:

Thioindigo red B.G (dichlorothionaphthene indigo) $C_6H_4Cl<\overset{CO}{S}>C=C<\overset{CO}{S}>C_6H_4Cl$; *thio-*

indigo red 3B (dichlorodimethylthionaphthene indigo)

thioindigo violet 2B (dichlorodimethyldimethoxythionaphthene indigo); *thioindigo orange R* (6:6'-diethoxythionaphthene indigo); and *thioindigo gray* (7:7'-diaminothioindigo). In general it may be said that the introduction of substituents such as OH, OCH₃, OC₂H₅, SCH₃, SC₂H₅, NH₂, &c., in the para- position to the sulphur atoms produces a deepening of the shade to blue-violet, greenish-black, &c. Substitution in the meta- position to the sulphur atoms produces yellower shades—orange, orange-brown and scarlet. Halogenation darkens the shade of thioindigo red.

Thioindigo scarlet R

obtained by the action of thioindoxyl on isatin contains the characteristic groupings of thioindigo red and of indirubin. When acted upon by bromine in sulphuric acid solution it yields a dibromo derivative which is placed on the market under the name of *thioindigo violet K*. The tribromo-amino derivative represents *thioindigo brown G*.

Ciba scarlet G (also known as *thioindigo scarlet 3G*) is a non-nitrogenous product, ob-

tained by the condensation of thioindoxyl with acenaphthene quinone and has the constitution

By the bromination of this dyestuff, *Ciba red R* results.

Of other indigoid dyestuffs, mention may be made of *Ciba yellow 3G*, which is obtained by boiling indigo with benzoyl chloride and copper powder in nitrobenzene, and to which the constitution

has been described. The complete change from blue to yellow is remarkable.

By the condensation of α -naphthol with α -isatinchloride, a compound is obtained with the following *ortho*quinonoid structure

and is, in a sense, also indigoid in character. The tribromo derivative is known as *Alizarin indigo 3R*. The corresponding compound from alpha anthrol and dibromoisatin is known as *Alizarin indigo G*.

The indigoid dyestuffs all behave very much like indigo towards reducing agents, i.e. they yield leuco compounds (corresponding to indigo white) which dissolve readily in caustic alkalis, and in this condition show affinity for the textile fibres. The affinity of the different dyestuffs for the cotton fibre varies, however, in each case, so that their successful application, especially in the production of mixed shades, requires a considerable amount of practical experience. The reducing agent employed for these colouring matters (in fact for all vat dyes other than indigo) is invariably sodium hydrosulphite, for although it is not the most economical, it is the most effective and convenient reagent for the purpose and yields vats which are free from sediment. In principle, the dyeing of cotton with these dyestuffs is the same as the dyeing of indigo in the hydrosulphite vat. The optimum temperatures vary, however, according to the individual dyestuff, from the ordinary temperature (as used for indigo) to temperatures as high as 70°. The range of shades obtainable contains almost every colour of the spectrum, and some of these vie in brilliancy with the basic colours. Most of the colours are characterised by great fastness, and are in this respect superior to indigo. Hitherto no indigoid black has been produced.

Although originally applied to dyeing and printing on cotton and other vegetable fibres, methods have been devised by which these colouring matters can be successfully applied in wool dyeing, by substituting ammoniacal

the caustic soda in the vat or neutralising the effect on the fibre of the caustic soda by the addition of some soluble oil (see H. Kämmerer, J. Soc. Dyers, 1913, 68).

In calico printing, the indigoid dyestuffs can be applied by methods similar to those employed for indigo, with the exception of the chromic acid discharge, which cannot be used owing to these dyestuffs being either not affected at all by chromic acid, on the one hand, or yielding imperfect discharges on the other. They can, however, be discharged by means of the formaldehyde compound of sodium sulfoxylate. For further information on the use of these colours in calico printing, see N. Evans, J. Soc. Dyers, 1913, 144.

Anthraquinonoid dyes.—The first of these dyestuffs brought into the market was *indanthrene blue*, a product formed by the action of molten caustic potash on β -aminoanthraquinone, and possessing the constitution

It is a dark blue compound insoluble in water, dilute acids, alkalis and most ordinary organic solvents. It can be obtained in well-defined crystals from its solution in quinoline or by sublimation. Oxidising agents convert it into the yellow azine

(containing 2 atoms of hydrogen less), but this is readily reconverted into the dyestuff by the action of reducing agents. Acted upon by hydrosulphite in presence of an excess of caustic soda, indanthrene blue yields a blue vat from which cotton and other vegetable fibres can be dyed in exceedingly fast shades of blue. The composition of the leuco compound of indanthrene blue and other anthraquinonoid vat dyes is not known with certainty, but it is evident from the behaviour of anthraquinone, alizarin and the non-nitrogenous anthraquinonoid dyes that reduction takes place in the $-\text{CO}-$ group, resulting in the formation of compounds analogous to oxanthranol

or the isomeric anthrahydroquinone

where in either case 2H would be required for the reduction. The further reduction to oxanthranol

requires 4H or its equivalent. In this connection it may be mentioned that in the quantitative estimation of alizarin by titration with titanous chloride in presence of sodium tartrate (J. Soc. Dyers, 1915, 241) the analogous reduction to desoxyalizarin

takes place, 4H being required.

To what extent the four $-\text{CO}-$ groups of indanthrene blue suffer reduction in the formation of a 'vat' is not known at the present time, and this applies also to the other anthraquinonoid dyes.

Halogen derivatives (Cl and Br) of indanthrene blue are also commercial articles and yield in dyeing greener shades of blue which are faster to bleaching powder than ordinary indanthrene blue (*v. INDANTHRENE*), as the introduction of halogen atoms renders the oxidation to the azine less easy. *Indanthrene blue GCD* an *dindanthrene blue GC* are the dichloro and dibromo derivatives respectively of indanthrene blue.

By the condensation of alizarin with 2:3-diaminoanthraquinone, a compound having the following constitution

is obtained, halogen derivatives of which come into the market under the names *algal blue* and *algal green*.

Flavanthrene or *indanthrene yellow* is formed as a by-product in the manufacture of indanthrene blue, but is obtained in much better yield, according to D. R. P. 138119, by the oxidation of β -aminoanthraquinone with antimony pentachloride in boiling nitrobenzene, or by the action of manganese peroxide in nitric acid solution (D. R. P. 141355). Flavanthrene has been shown to possess the constitution

and comes into the market in the form of a yellow paste. With caustic soda and hydrosulphite (or other reducing agents) it yields a deep cobalt-blue vat from which cotton takes up the leuco compound and is dyed, after exposure to the air, a fast yellow. The halogen derivatives of flavanthrene dye redder shades than flavanthrene itself.

That nitrogen and sulphur are not essential

constituents of vat dyes is shown by the fact that *pyranthrone* or *indanthrene golden orange G*

obtained by the condensation of two molecules of 2:2'-dimethyl-1:1'-dianthraquinonyl behaves in exactly the same manner towards reducing agents and in dyeing as the other vat dyes of this series. By the introduction of halogens into this dyestuff the shade is altered towards red. Thus, the brominated product represents *indanthrene scarlet G*.

By the alkaline condensation of two benzanthrone molecules, vat dyes are obtained, the simplest representative of which (*violanthrene BS*) is represented by the constitution

which, when nitrated, yields *indanthrene green*. This vat dye produces a green on cotton which is not very fast to light. *Indanthrene violet RT*, which dyes very fast shades, is a halogenated violanthrene. *Violanthrene R extra* is obtained by fusing halogen derivatives of benzanthrene with alcoholic potash. It is represented by the constitution

Indanthrene violet RB and *indanthrene violet B* are the dichloro and dibromo derivatives of this violanthrene.

Some of the dyestuffs of this series are derivatives of aminoanthraquinones and are represented by comparatively simple constitutional formulae. Thus, *algal yellow WG* is α -benzoylaminoanthraquinone

whilst *algal pink R* is the benzoyl derivative of a hydroxyaminoanthraquinone

A variety of shades are produced by the introduction of further groups such as OCH_3 , NH_2 , additional OH groups, &c., into the anthraquinone molecule, followed by benzoylation. Succinyl derivatives are also used. An example of these is the dyestuff known as *algal yellow 3G*, which is the succinyl compound of diamino-dianthraquinone

It is noteworthy that the arylaminoanthraquinones do not act as vat dyes for cotton, although some of them are, in the form of the sulphonic acids, valuable wool dyes. In this connection it may be mentioned that whereas alizarin is quantitatively reduced by titanous chloride in presence of Rochelle salt to desoxy-alizarin, alizarin orange cannot be reduced further than to β -aminoalizarin.

Another class of anthraquinonoid dyes, the anthraquinone acridones, are obtained by condensing 1:2 chloroanthraquinone carboxylic acids with aromatic amino compounds, followed by treatment with concentrated sulphuric acid. *Indanthrene violet 2B* is a member of this class. It is represented by the constitution

Some of the *sulphide colours* (q.v.) are also classed as vat dyes, though they do not appear to bear any relationship to the indigoid or anthraquinonoid dyestuffs as far as constitution is concerned. The points of similarity are the use of hydrosulphite to form a vat and the fastness of the resulting colours on cotton. Of these dyestuffs the best known is *hydron blue*, which is obtained by melting the indophenol of carbazol (from *p*-nitrosophenol and carbazol) with a sodium polysulphide rich in sulphur. The dyeing is done at an elevated temperature (50° - 70°), and shades are obtained which resemble indigo, though they are claimed to be faster. Some vat dyes obtained from anthracene or its derivatives, such as *algal brown B*, *indanthrene olive G*, and the *cibacron* colours are also sulphide dyes of unknown constitution.

The anthraquinonoid dyes are employed in cotton dyeing much in the same way as the indigoid dyes. Generally speaking, they require, however, a much larger amount of caustic soda in the vat and are not dyed cold, but at a

temperature of 50°-60°. In dyeing light shades, the dye-bath is generally exhausted under these conditions. After dyeing, the goods are soaped hot, a process which in most cases considerably enhances the brilliancy of the colour. With some of the colours, the fastness to bleaching powder is increased by steaming under pressure after dyeing. Although no black anthraquinonoid dyestuff is known, a black of extraordinary fastness can be obtained on cotton by dyeing it first indanthrene green and then subjecting the dyed material to the action of bleaching powder. The colours obtained with the dyes of the anthraquinonoid series are generally somewhat faster to light than those obtained with the indigoid dyes. They are not applicable to wool dyeing owing to the necessity of keeping the vat strongly alkaline with caustic soda, with the inherent risk of damaging or destroying the fibre. It has been suggested that a preliminary treatment of the wool with formaldehyde would obviate this difficulty.

In calico printing, the anthraquinonoid dyes are largely used for some of the best classes of work. The usual method of using the indanthrene colours is to print a colour containing the vat dye, stannous chloride, ferrous sulphate and thickening, and after drying to pass rapidly through a hot strong solution of caustic soda. The fixation may also be effected in one operation by using a printing colour containing the vat dye, hydrosulphite-formaldehyde and soda ash, after which the goods are steamed for 5-7 mins. in air-free steam. The glucose process, as described for indigo, is also applicable to vat dyes in general.

In steaming or 'ageing' the vat dyes, it sometimes happens that the colours do not develop satisfactorily on subsequent exposure to the air, and faulty goods thus result. This is due to over-reduction of the vat dye to a stage at which neither air contact nor oxidising agents will develop the colour. See Reinking: Exothermic reactions in the rapid ager, J. Soc. Dyers, 1922, 306.

By the introduction of the vat dyes the public demand for fast colours, especially in dyes and printed cotton and linen fabrics, has been met, and it is now possible to obtain by means of them almost any shade fast to washing, light, perspiration, rubbing, and even bleaching powder. It should, however, not be taken for granted that a vat dye is of necessity a fast colour. Those on the market have, however, generally been carefully tested and selected by the makers and usually possess this attribute. Many of the vat dyes are so fast that they can be put through the full bleaching process for cotton pieces without suffering any material diminution of intensity and brilliancy, and advantage is taken of this in the production of white fabrics with coloured stripes or figures. Whereas it was formerly necessary, in order to obtain these effects, to bleach both warp and weft before weaving, the bleaching is now largely effected in the piece and considerable economy is realised. With the exception of indigo, the vat dyes are still too expensive to admit of their being employed for any but the best class of work. This is due in part to the high cost of manufacture, but more especially to the fact that most of them are tinctorially weak, as com-

pared with, for instance, the basic and direct cotton colours. Even indigo itself shows this drawback, but most of the other vat dyes show it to a greater extent.

For the identification of the vat dyes in dyed and printed fabrics, see A. G. Green and G. H. Frank (J. Soc. Dyers, 1910, 83), also G. E. Holden (*ibid.* 1909, 47), A. G. Green, W. Gardner, L. Lloyd, and G. H. Frank (*ibid.* 1913, 227), and J. I. M. Jones and W. Kilby (*ibid.* 1925, 127). Indigo can readily be distinguished from the other vat blues by dissolving the fabric in warm 80 p.c. sulphuric acid. The solution is poured into water and filtered through a small asbestos filter. After washing and drying, the residue on the filter is heated to about 100° with concentrated sulphuric acid and again poured into water and filtered. Under these conditions, the indigo is sulphonated and passes into the filtrate with a bright blue colour, whereas the other vat blues remain unaffected. E. K.

VAUQUELINITE. Native lead and copper chromate.

VAUXITE AND PARAVAUXITE. These occur on wavellite in brecciated tin-veins in rhyolite at Llallagua, Oruro. Vauxite occurs as radiating aggregates of sky-blue, tridinic crystals with $a:b:c=1.1510:1:1.2624$, $\alpha=99^{\circ}32'$, $\beta=102^{\circ}14'$, $\gamma=110^{\circ}14'$; $d\ 2.375$, $H\ 3\frac{1}{2}$; refractive indices $\alpha\ 1.551$, $\beta\ 1.555$, $\gamma\ 1.562$, optically positive. Paravauxite forms colourless, triclinic crystals of prismatic habit with good $b\ (010)$ cleavage; $a:b:c=0.5058:1:0.6882$, $\alpha=97^{\circ}42'$, $\beta=110^{\circ}22'$, $\gamma=100^{\circ}56'$; $d\ 2.291$, $H\ 3$; refractive indices $\alpha\ 1.554$, $\beta\ 1.558$, $\gamma\ 1.573$, optically positive. Analyses by J. E. Whitfield gave I for vauxite and II for paravauxite.

				H ₂ O at 104°	H ₂ O above 104°
FeO	MnO	Al ₂ O ₃	P ₂ O ₅	104°	104°
I. 19.34	0.18	14.89	31.33	3.68	30.24
II. 15.47	—	17.89	29.80	16.40	20.34

The minerals are readily soluble in hydrochloric acid. The water content of the paravauxite varies considerably with the humidity of the atmosphere. Formulas:

Vauxite: $4\text{FeO} \cdot 2\text{Al}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 24\text{H}_2\text{O} + 3\text{H}_2\text{O}$.

Paravauxite:

$5\text{FeO} \cdot 4\text{Al}_2\text{O}_3 \cdot 5\text{P}_2\text{O}_5 \cdot 26\text{H}_2\text{O} + 21\text{H}_2\text{O}$.

(Samuel G. Gordon, Proc. Acad. Nat. Sci. Philadelphia, 1923, 75, 261-270; Chem. Soc. Abstr. 1923, 124, ii. 646).

VEGETABLE BUTTER v. **BASSIA OILS**; also **OILS, FIXED, AND FATS**.

VEGETABLE ETHIOPS. A form of charcoal obtained by the incineration of *Fuci*.

VEGETABLE FATS v. **OILS, FIXED, AND FATS**.

VEGETABLE IVORY. The fruit of *Physalis macrocarpa* (Ruiz. and Pav.) found in Colombia, South America.

VEGETABLE PARCHMENT v. *Parchment paper*, art. **CELLULOSE**.

VEGETABLE SPERMACEYL. *Insect wax*, v. **WAXES**.

VELOCITY OF REACTION v. **CHEMICAL AFFINITY**.

VELLOSINE v. **PERIBO BARK**.

VENETIAN CHALK v. **STREATH**.

VENETIAN LAKE. *Crimson lake* v. **PREMENTS**.

VENETIAN RED. Ferric oxide.

VENETIAN WHITE. A white lead pigment containing a large percentage of barium sulphate.

VENTILAGO MADRASPATANA (Gerten.) is a large climbing shrub belonging to the order *Rhamnaceae*, the root-bark of which furnishes a dyestuff much valued in Southern India. It is very common in the Western Peninsula from the Konkan southwards, as well as in Ceylon and Burma, and, according to Lostard, it is collected in Mysore at certain periods of the year and exported to other districts of India.

The following are a few of its vernacular names: pitti (*Hindi*); raktapita (*Bengali*); pappili-chakka, surralpattai (*Tamil*); popli-chukai (*Kan*); lokandi, kanwai (*Bomb*).

The root-bark appears as dark purplish-brown scales, ribbons, or filaments, the dust from which, when it is ground to powder, irritates the throat in a marked manner. When treated with boiling water or alcohol it gives a red solution, which on addition of caustic alkali, changes to a deep crimson.

Perkin and Hummel (Chem. Soc. Trans. 1894, 65, 923), who examined this dyestuff, extracted the root-bark with carbon disulphide, and obtained in this manner a resinous colouring matter, *ventilagin*, together with the crystalline non-tinctorial substances described below.

Ventilagin $C_{11}H_{14}O_6$ consists of a reddish-brown brittle resin which, when distilled with zinc-dust, gives *a*-methyl-anthracene, and when treated with zinc-dust in alkaline solution behaves as a derivative of *methyl-anthraquinone*. Dilute alkalis dissolve it with a purple-violet coloration, and the corresponding salts are obtained as violet precipitates on adding sodium or potassium chlorides to these solutions. According to Perkin and Hummel, *ventilagin* is possibly allied to *alkannin* $C_{15}H_{14}O_8$, the colouring matter of *alkanet*, *Anchusa tinctoria* (Lam.), and may differ from this merely by the possession of two additional hydroxyl groups.

Emodin monomethyl ether $C_{15}H_{12}O_5$, m.p. 200°, consists of orange-red needles, and is identical with that subsequently isolated from the root of the *Polygonum cuspidatum* (Sieb. and Zucc.) (Perkin, Chem. Soc. Trans. 1895, 67, 1064). A similar, if not identical, substance was isolated by Schwabe (Arch. Pharm. 1888, 26, 569), and by Thorpe and Miller (Chem. Soc. Trans. 1892, 64, 6) from the bark of the *Rhamnus frangula* (Linn.), and it is also present in rhubarb and the *Rumex ecklonianus* (Lc.) and Goa powder.

Trihydroxy-a-methyl-anthranol monomethyl ether (A), $C_{15}H_{12}O_6$, colourless needles, decomposes about 260° before melting, and is soluble in alkaline solutions with a yellowish-brown coloration. On gentle oxidation with chromic acid it is converted into emodin methyl ether, m.p. 300° (Lc.), and the same reaction takes place when its alkaline solution is oxidised with hydrogen peroxide. It closely resembles the dehydro-emodin-anthranol monomethyl ether, subsequently isolated from Goa powder by Tatin and Clewer (Chem. Soc. Trans. 1912, 101, 280).

Trihydroxy-a-methylanthranol monomethyl ether (B), $C_{15}H_{12}O_6$, pale yellow needles, m.p. 173°, when oxidised with chromic acid is also

converted into the emodin methyl ether, m.p. 200°. As two methyl anthranols are capable of existence, the isomerism of these compounds may possibly be thus explained:—

Substance $C_{15}H_{12}O_5$, orange-red crystalline powder, m.p. 275°–280°, is soluble in alkaline solutions with an orange-red coloration, and when heated with zinc-dust gives a hydrocarbon which resembles *a*-methyl-anthracene.

Substance $C_{17}H_{12}O_5$? is a chocolate, crystalline powder, soluble in dilute alkali with a yellow coloration, and this solution, on exposure to air, deposits a blue amorphous precipitate.

Dyeing Properties.—On striped printed calico the root-bark gives with alumina mordant a claret-red, not unlike that of alizarin bordeaux; with iron mordant a greyish-lilac, which in strong colours approaches a black; and with a mixture of the two a very purplish dark chocolate. The colours are moderately fast to soap, although considerably behind the alizarin colours in this respect. On oil-prepared calico *ventilago* gives with alumina mordant a rich claret-brown, with chromium mordant a very black-purple, and with iron mordant a good purplish-black shade. On wool chromium mordant gives a good purplish-brown, alumina a bordeaux red, tin a brighter red similar to an alizarin red, and iron mordant gives dark dull purple and black. On silk similar colours are produced. No difficulty is experienced in dyeing with *ventilago*, and no additions to the dye-bath are necessary, except in the case of wool, with which it is desirable to add calcium acetate in order to correct the strong acidity of the mordanted fibre. Owing to the slight solubility of the colouring matter in water, the dyeing does not commence until the temperature reaches 70°–80°. The root-bark appears to contain from 8–10 p.c. of *ventilagin*.

A. G. P.

VERATRABINE, VERATRIDINE, VERATRINE v. CEVADINE.

VERATROLE (*o*-dimethoxybenzene)

is best obtained by dissolving catechol (100 grms.) in methyl alcohol (200 grms.) mixed with 75 grms. of methyl sulphate. The mixture is cooled to –5°, and 150 grms. of potash dissolved in 350 grms. of water are then added all at once. In 3 mins. the methylation is complete. The product is diluted with water, extracted with ether, and the extract is dried and distilled (Perkin and Weizmann, Chem. Soc. Trans. 1906, 1656). Veratrole is also formed by the distillation of guaiacol with lead oxide (Fischer and Silberbach, Ber. 1904, 37, 2149). Veratrole forms a crystalline mass, m.p. 15°, b.p. 205°. It yields a number of halogen derivatives (Cousin, Compt. rend. 1898, 127, 759; 1902, 135, 967; Ann. Chim. 1898, [vi] 13, 483); also nitro derivatives (Cousin, Compt. rend. 1902, 134, 290; 135,

967; Salway, Chem. Soc. Trans. 1909, 1163), a *phthalide*

(Perkin and Weizmann, l.c.) and other compounds (Kropp and Decker, Ber. 1909, 42, 1184).

Veratrole reacts with hippuryl chloride in presence of aluminium chloride, forming a crystalline product, m.p. 155°

from which valuable therapeutic products are said to be obtained (D. R. P. 185596; Frdl. 1905-1907, 1184).

For other literature, see Simonsen, Chem. Soc. Trans. 1917, 111, 69, 220; 1918, 22, 782; Jones and Robinson, *ibid.* 1917, 111, 903.

VERBENALIN. A crystalline glucoside found in *Verbena officinalis* (Linn.), m.p. 181.5°; $\alpha_D = -180.3^\circ$. Hydrolysed by emulsin, yielding dextrose (Bourdier, J. Pharm. Chim. 1908, 27, 49, 101).

VERDIGRIS, VERT-DE-GRIS, VERT DE MONTPELIER. Basic acetates of copper v. ACETIC ACID.

VERDITE. An ornamental stone of a rich green colour consisting mainly of hydrated magnesium silicate coloured by chromium. It represents a serpentine rock more or less completely altered to talc. The chromium is probably present as the chrome-mica fuchsite, which was no doubt derived from chromite. The rock shows mottlings of yellowish-green and bluish-green with splashes of brown and yellow, and it takes a high polish. Sp.gr. 2.8; H. 3½. It occurs in the Jamestown series (Swaziland system) of chloritic and talcose schists; and is obtained from small quarries at several places on the banks of the Kaap and North Kaap rivers near Barberton in the Transvaal, and more particularly at the Verdite mines at Jamestown near Barberton, which are worked for talc with gold as a by-product (A. L. Hall, The Geology of the Barberton Gold Mining District, Union of South Africa, Geol. Survey, 1918, Mem. No. 9). L. J. S.

VERDITER, GREEN AND BLUE, v. COPPER.

VERIDIAN. *Guignet's green v. CHROMIUM.*

VERJUICE. A kind of vinegar containing malic acid made from the juice of the crab-apple.

VERMILION v. MERCURY.

VERMILIONETTE. A red pigment made by adding eosin to white lead, barium sulphate or zinc white.

VERNINE $\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}_2\cdot 2\text{H}_2\text{O}$ found by Schulze (Zeitsch. physiol. Chem. 1885, 9, 420) in seedlings of *Vicia sativa*, and later in a number of other plants. Is identical with *guanosine*, obtained by Levene and Jacobs (Ber. 1909, 42, 2469) by the hydrolysis with water of guanylic acid. M.p. 237°, $[\alpha]_D^{20} = -60.52^\circ$ in alkaline solution. It is hydrolysed by acids to guanine and a pentose, presumably *d*-ribose (Schulze and Trier, Zeitsch. physiol. Chem. 1910, 70, 143).

From the green leaves and berries of the coffee tree a pentoside has been isolated, containing guanine, which is probably identical with *guanosine* obtained by Schulze and Trier from other plants and from 'nucleic acid' by Levene and Jacobs. It is suggested that the

caffeine in the leaves and berries of the coffee tree is derived from *guanosine*, the latter being converted successively into *guanine*, *xanthine*, and *caffeine* by the action of enzymes (T. de A. Camargo, J. Biol. Chem. 1924, 58, 831; J. Soc. Chem. Ind. 1924, 43, B. 312), v. **ESGOT**.

G. B.

VERONAL. Trade name for diethylmalonylurea ($\text{C}_2\text{H}_5)_2\text{N}[\text{CO}\cdot\text{NH}]_2\text{CO}$, prepared by the condensation of urea and diethyl-malonyl chloride. A white crystalline powder of bitter taste, m.p. 191°. Soluble in water, ether, acetone, acetic ester. Used as a soporific (v. **SYNTHETIC DRUGS AND PYRIMIDINES**). For the chemical detection of veronal poisoning, v. Macadie, Pharm. J. 1913, 90, 134; Richards, Analyst, 1919, 44, 192; van Itallie and van der Veen, Pharm. Weekblad, 1919, 56, 1142; J. Pharm. Chim. 1919, [vii.] 20, 337. Veronal and the malonylureas generally readily condense with xanthidrol to form crystalline dioxanthyl derivatives which may be used for the characterisation and identification of the malonylureas by observation of their melting-points (Fabre, J. Pharm. Chim. 1922, 26, 241). The veronal derivative melts at 245°-246°. Thus, if a solution of 1 gm. of veronal and 2 grms. of xanthidrol in acetic acid is boiled for a few seconds and cooled a crystalline precipitate of a dioxanthylated derivative is formed which can be purified by washing with boiling alcohol and its melting-point determined. In toxicological investigation the veronal has first to be isolated from the viscera. From 100 to 150 grms. of material are digested on a water-bath for 3 hours with a mixture of 95 p.c. alcohol and 5 grms. of tartaric acid, cooled, filtered and concentrated by distillation. The residue is dissolved in 50 c.c. of distilled water, and after being made slightly alkaline, the solution is shaken up several times with ether to eliminate fatty matter. After acidulation with dilute sulphuric acid the liquid is evaporated, and the residue taken up three times with ether which dissolves the veronal. The residue from the extract is purified by dissolving it in water, heating with animal charcoal, filtering and crystallising the filtrate. After several crystallisations the melting-point can be determined. The search for these hypnotic compounds may also be made in the urine, since 60 to 65 p.c. of the veronal absorbed can be found in the urine excreted during the four following days (Analyst, 1922, 47, 523).

VEROPYRIN. Trade name for a mixture of ethylmorphine hydrochloride, veronal-sodium and calcium acetylsalicylate.

VERT DE GUIGNET v. CHROMIUM.

VERVAIN. Cymylacetic aldehyde (1-isopropyl-4-ethanalbenzene

possesses a strong odour resembling vervain, but not of such delicacy as that of the plant. As it may be easily and economically prepared, it is anticipated that it will be extensively used in synthetic perfumery. It is obtained by condensing magnesium cymyl chloride with ethyl orthoformate, hydrolysing the product with dilute sulphuric acid, and separating the aldehyde by means of its bisulphite compound. It is a pale yellow liquid, b.p. 243°C. (L. Bert.

Comptes rend. 1923, 177, 550-551; J. Soc. Chem. Ind. 1923, 42, 1099 A).

VESALVINE. Syn. for hexamethylenetetramine.

VESIPIRIN. Trade name for phenyl acetosalicylate, v. SALICYLIC ACID and SYNTHETIC DRUGS.

VESTORIEN v. EGYPTIAN BLUE; also ENAMELS.

VESUVIANITE or **IDOCRASE.** A mineral consisting of a complex silicate of calcium and aluminium, together with iron, magnesium, water, fluorine, boron, &c. F. W. Clarke's formula is $R'_4Al_2Ca_2Si_4O_{24}$, where $R'_4 = Ca_2, (AlOH)_2, H_2$, &c. Crystals are tetragonal and usually green or brown in colour; sp.gr. 3.35-3.45; H. 6½. The mineral is of common occurrence in contact-metamorphic rocks, particularly crystalline limestones. Lustrous, brown crystals are common at Monte Somma, Vesuvius (hence the name vesuvianite). Green crystals from Ala in Piedmont are cut as gems at Turin. A compact, massive variety has been found abundantly as blocks and boulders, measuring up to 6 by 3 ft., at several places in California (Siskiyou, Butte, Fresno, and Tulare counties). This has been called *californite* (G. F. Kunz, 1903), and is much used as a gemstone and for larger ornamental objects. It is somewhat translucent, takes a high polish, and ranges from bright green to yellowish-green and white in colour, thus closely resembling jade in appearance (D. B. Sterrett, Min. Res. U.S. Geol. Survey, annual reports for 1909 and 1910.)

L. J. S.

VICINE $C_{10}H_{16}O_4N_4H_2O$ was discovered by Ritthausen (J. pr. Chem. 1870, [ii.] 1, 336; 1873, [ii.] 7, 374; 1881, [ii.] 24, 202) in the seeds of *Vicia* spp. According to Levene (J. Biol. Chem. 1914, 18, 305; Levene and Senior, *ibid.* 1916, 25, 607) it is a mononucleoside, or glucoside of 2:5-diaminotetrahydropyrimid-4:6-dione (2:5-diamino-uracil) of the following constitution:

It forms needles, m.p. 242°, $[\alpha]_D^{25} -11.7^\circ$. It is hydrolysed by 20 p.c. sulphuric acid at 100° to dextrose and *divicine* (of Ritthausen) = 2:5-diamino-uracil $C_4H_4O_2N_4$. Compare also Johnson, J. Amer. Chem. Soc. 1914, 36, 337; Johnson and Johns, *ibid.* 1914, 36, 545; Fischer, Ber. 1914, 47, 2611; Winterstein, Zeitsch. physiol. Chem. 1919, 105, 258.

Convicine $C_{10}H_{14}O_4N_4H_2O(?)$ was also found by Ritthausen in vetch seeds and yields on hydrolysis alloxantin, ammonia and a hexose.

G. B.

VIGIANIN v. GLUCOSIDES.

VIGIANOSE v. CARBOHYDRATES.

VICTORIA YELLOW. *Gold yellow, Aniline orange, Saffron surrogate.* This colouring matter, introduced by Mottenswei, under the name of *Victoria yellow* or *aniline orange* (Wag. Jour. 1869, 583), consists of the potassium or ammonium salt of a dinitrocresol (Martius and Wichelhaus, Ber. 2, 306; v. Sommaruga, *ibid.* 2, 579). It is prepared by heating cresol, with three times its weight of sulphuric acid at 100°, until the product is soluble in water. After removing the excess of sulphuric acid by

means of barium carbonate, the cresol-sulphonic acid is converted into potassium salt, which in the dry state is nitrated by introducing it rapidly into about three times its weight of dilute nitric acid (sp.gr.=1.2), and is then poured into water, neutralised with potassium carbonate, and the resulting potassium dinitrocresol crystallised out. Obtained in this way, the colouring matter is a mixture of the potassium salts of dinitro-*o*- and dinitro-*p*-cresol, and varies in colour according to the proportions of these. Thus Victoria yellow is yellowish in colour, and consists chiefly of the potassium salt of dinitro-*o*-cresol (m.p.=86°), which crystallises in yellow needles (Wichelhaus, *ibid.* 7, 176; Piccard, *ibid.* 8, 685), whereas saffron surrogate is distinctly reddish in colour, and consists chiefly (80 p.c. according to Piccard) of the potassium salt of dinitro-*p*-cresol (m.p.=84°), which crystallises in red needles (Armstrong and Field, Chem. News, 27, 318; Hofmann and v. Miller, Ber. 14, 567; Staedel, *ibid.* 14, 900, 906; Nölting and Salis, *ibid.* 14, 986).

Victoria yellow is soluble in water and dyes wool and silk orange, but owing to the fugitive nature of the colour is no longer employed for this purpose. Saffron surrogate is still used to some extent as a colouring matter for butter, margarine, vermicelli, cheese, &c. (Piccard), but this is to be deprecated, since Weyl's experiments show that the compound is poisonous (Ber. 20, 2835; 21, 512). Cf. NITROPHENOLS AND THEIR HOMOLOGUES.

VIENNA BLUE. Cobalt blue v. PIGMENTS.

VIENNA GREEN. Emerald green v. PIGMENTS.

VIENNA PASTE. A mixture of lime and potash used as a caustic to extirpate malignant growths.

VIFERRAL. A polymerised chloral

A white powder, m.p. 153°-155°, sol. in water. Used as a hypnotic.

VIMOPYRIN. Trade name for *p*-phenetidine tartrate.

VINASSE v. SUGAR.

VINE BLACK. Blue black v. PIGMENTS.

VINEGAR, AROMATIC, v. ACETIC ACID.

VINEGAR PLANT. v. ACETIC ACID; FERMENTATION.

VINOLINE. A mixture of coal-tar reds, mostly rosaniline salts, used for colouring wines.

VINOPYRIN v. SYNTHETIC DRUGS.

VIOFORM. Trade name for iodochloro-hydroxyquinoline. A greyish-green powder used as a bactericide and antiseptic, and as a substitute for iodoform (v. SYNTHETIC DRUGS).

VIOLANE. A variety of the pyroxene (q.v.) group of minerals of a rich violet colour, and occasionally used as an ornamental stone. It is a silicate of calcium, magnesium, aluminium, sodium, iron, and manganese (about 2 p.c. MnO, to which the colour is due). It sometimes forms prismatic crystals of the monoclinic system, but more often compact masses with a lamellar or fibrous structure. It is found, together with other silicates coloured by manganese, in the manganese mines at San Marcel in the Aosta valley, Piedmont. L. J. S.

VIOLANIN v. ANTHROCTANINS.

VIOLANTHRENE v. INDANTHRENE.

VIOLET DE PARIS or VIOLET DIRECT.
Methyl violet v. TRIPHENYLMETHANE COLOURING MATTERS.

VIOLET 5B, 6B, v. TRIPHENYLMETHANE COLOURING MATTERS.

VIOLET R and RR and 5R. *Hofmann's violet v. TRIPHENYLMETHANE COLOURING MATTERS.*

VIOLIN. An emetic substance contained in the common violet, supposed to be identical with emetine from ipecacuanha root.

VIOLINE or VIOLEIN. A synonym for mauve or aniline purple.

VIOLONES. Coloured anhydro-bases obtained by acting upon pyrylium salts with *p*-hydroxylated phenyl radicals by weak alkalis Dilthey and Burger, Ber. 1921, 54 [B], 825).

VIOLURIC ACID v. PYRIMIDINES.

VIRIDIAN. Hydrated chromium sesquioxide, v. CHROMIUM.

VIRIDINIC ACID v. TANNINS.

VIRIDITE v. THURINGITE.

VISCOSE v. SILK, ARTIFICIAL.

VITAMINS. To deal seriously from a standpoint strictly chemical with substances which have never been isolated in a pure condition is, of course, impossible. The constitution of the peculiar dietary constituents which have been called Accessory Food Factors (Hopkins), or Vitamines (Funk) is as yet entirely unknown. They are not, however, merely hypothetical substances. The evidence for their objective existence is ample enough, but as this evidence is in part, so to speak, of a negative kind, and in any case depends upon studies in which impure preparations have been perforce employed, it calls for critical consideration. The fundamental facts which make necessary a belief in the existence and physiological importance of nutrients differing in kind from those which until lately were alone recognised, can, however, be quite briefly enumerated.

Until fifteen years ago it was generally believed that the efficacy of a diet could be determined by three essential criteria. The first was the obvious one that it should provide enough potential energy for the current dynamic needs of the body. The second was that it should contain a certain minimum of protein, to exercise specific functions which the non-nitrogenous foodstuffs cannot subserve, and the third called for a balanced mineral supply. We now know that these criteria are insufficient. Although data from highly quantitative studies of human and animal nutrition have long existed in great numbers, these data were obtained during the administration of natural food materials. The fats, carbohydrates and proteins contained in these diets were accurately calculated and the effects of their variation evaluated; but that these constituents (with the necessary minerals) were alone responsible for the successful maintenance of the body was an unjustifiable assumption. Quantitatively they account for nearly the whole of the necessary supply, but hundreds of recent experiments and observations have shown that there are other substances in natural foods which, though present in only very small quantities, are yet absolutely essential for proper nutrition. These are the substances which,

pending a knowledge of their nature, it is agreed to call vitamins.

The assumption mentioned in the last paragraph was unjustified, because the food constituents which were thought to cover all needs were never administered in a pure form. It can be shown with the greatest ease that if an animal be supplied with purified protein and pure fats and carbohydrates, together with a salt mixture proved in other associations to be efficient, the food may be well eaten, well digested, and even fully metabolised, yet the animal's nutrition fails, and it finally dies. What, however, endows the phenomena we are considering with their fullest significance is the circumstance that the purified foodstuffs just mentioned become wholly efficient and fully maintain growth, health and activity when material is added to them in amounts so small compared with the whole quantity of food consumed that it would seem almost negligible. This material must comprise at least three and probably more vitamins. The extraordinary importance of their nutritional effects and the remarkably small concentration in which these effects are produced are the characteristics which supply the only definition of vitamins at present available.

While, during the first decade of the present century, the facts just mentioned were being established by feeding experiments done mainly upon animals, evidence giving precisely similar indications arose from a new and enlightened study of certain human diseases. It was almost a pure coincidence that these two lines of evidence should have become available contemporaneously. Clear indications showing that the disease, *Beri Beri*, which mainly—though by no means exclusively—attacks rice-eating populations, is intimately related to diet, was indeed brought forward by Eijkman so far back as 1897. He showed that a condition very similar to the human malady could be induced in fowls by feeding them upon an exclusive diet of polished white rice, while a cure was at once established by adding rice polishings to the diet, or by replacing the polished grain by whole grain. The suggestion given by these experiments was followed up and observations made upon a great number of prisoners in the gaols of Java, and the fact established that *Beri Beri* is far more frequent among these eating rice deprived of the grain cortex than among those receiving the whole grain. This work was fully confirmed by that of W. Fletcher, published in 1907-8 (*Lancet*, 1907, 1776). The time was not even then ripe, however, for the simple interpretation of the facts. Only when later studies were published, and in particular those of Frazer and Stanton (*Studies from the Inst. for Med. Research, Federated Malay States*, No. 12, 1911) did the clear conception arise that the cortex of rice grain, unlike the endosperm, contains a specific substance of unknown nature, but certainly essential to life. It can be supplied in many other foodstuffs besides cereals, but the circumstance that it has a local distribution in grains, together with the one-sided character of Eastern dietaries, conspired to bring the facts to light. The disease scurvy yields even clearer evidence that healthy nutrition calls for a supply of a substance, or substances, not comprised in the ordinary categories of foodstuffs. Its

incidence and cure might, it would seem, have led long ago to a conception of what we should now call a vitamin. Preconceptions and prejudices led, however, to other explanations of the disease. Ultimately, however, though not until about 1912, the convergence of the pathological evidence and that obtained from feeding experiments led to a somewhat sudden emergence of the belief that nutrients must exist with the potent qualities now attributed to vitamins.

Though all attempts to isolate the substances with which we are concerned have so far failed, preparations have been made in a highly concentrated form, and work which, in a limited sense at least, is quantitative, has been done upon them. Certain of the properties of the vitamins are well characterised in a chemical sense, and there is every reason to believe that they will ultimately be isolated. It is as yet impossible, as already admitted, to define them except in terms of their physiological properties. They arise during the growth of the plant. For the animal they are essential, indispensable nutrients. There is clear evidence that at least three distinct members of the class exist and strong suggestions for the existence of a fourth. Each has its own peculiar influence in the body. While we are ignorant of their nature any scheme of nomenclature must be unsatisfactory. It is best to use names without special connotations, and to speak simply of the A-, B- and C-vitamins, respectively, is a justifiable custom.

The B-Vitamin.—Although this substance has received as a prefix the second letter of the alphabet, it will be convenient to deal with it first. It is the so-called 'water soluble vitamin,' or anti-neuritic factor. If it be absent from the diet, a young animal fails to grow, and soon, like the adult animal, develops symptoms which depend upon the occurrence of degenerative changes in the nervous system. In the human individual these symptoms in their more extreme form constitute the picture of Beri Beri. The substance, as its earliest name betokens, is freely soluble in water. It is also soluble in 80 p.c. alcohol, though much less so, if at all, in absolute alcohol. Acidified methyl alcohol extracts it from many tissues containing it. Insoluble in other ordinary organic solvents, it shows a rather remarkable solubility in oleic acid or olive oil (Myers and Voegtlin, *Proc. Nat. Acad. of Sc.* 1920, 6, 3). It is precipitated from aqueous solution by precipitants which throw down organic bases: phosphotungstic acid, for instance, or silver nitrate plus barium hydroxide. This behaviour, together with the fact that very active preparations obtained by the use of these precipitants contained nitrogen, led Funk to believe that the active substance was a base, and, in consequence, he suggested the name vitamins, which is now attached to all members of the class. Such precipitation may not be specific, however, but may be due to adsorption. The substance is freely adsorbed, for instance, by fuller's earth, and may be concentrated by its use. This property also allows of its separation from other vitamins (Harden). A silver compound has been prepared with high physiological potency (Seidell, *Pub. Health Reports, Washington, 1921*). The B-vitamin is a relatively stable substance, showing considerable

resistance to destruction by heat. It also resists the effects of acids, but is much more sensitive to alkalis (McCollum and Simmonds, *J. Biol. Chem.* 1918, 33, 55; Daniels and McClurg, *ibid.* 1919, 37, 201). Several attempts to isolate it have been described. Funk obtained, from extracts of rice polishings and yeast, crystalline products capable of curing birds suffering from polyneuritis due to feeding exclusively upon polished rice (*J. Phys. Chem.* 1913, 46, 173). Such results proved, indeed, the potency of almost infinitesimal quantities of the active substance, but unfortunately did not lead to its isolation. Funk believed at first that he had proved it to be a pyrimidine derivative, but when his crystalline preparations were fully purified they were found to be inactive and to consist largely of nicotinic acid, which itself is certainly without the characteristic activity. The purine base adenine has been stated to possess the properties of this vitamin, the remarkable statement being made that this base exists in two forms—one a physiologically active form, which by molecular rearrangement may pass over into a second and inactive form. Certain synthetic α -hydroxy-pyridines have been said to have similar properties (Williams, *J. Biol. Chem.* 1916, 25, 437; Williams and Seidell, *ibid.* 26, 431). These statements have been controverted, however (Harden and Zilva, *Bio-Chem. J.* 1917, 11, 172; Voegtlin and White, *J. of Pharm. and exp. Ther.* 1916, 9, 155). It must be admitted that all attempts to isolate the vitamin or to relate it to known substances have hitherto failed.

The B-vitamin is widely distributed in the tissues of plants, and is stored, though in low concentration, in many animal tissues. In the yeast cell it is especially abundant. As already pointed out, in the grains of cereals it has a local distribution, being present in the germ and pericarp, but not in the endosperm. The relative amounts present in various natural foods have been ascertained by determining on standard lines the minimum quantity of each food which is capable of preventing or curing polyneuritis in birds. The available data will be found in the Report upon Vitamins issued by the Medical Research Council. Such experiments consume much time. Endeavours to use its supposed effects upon the rate of growth of yeast as a measure of its amount have on the whole proved disappointing (*cf.* Funk and Dubin, *J. Biol. Chem.* 1920, 44, 487; McDonald and McCollum, *ibid.* 1921, 46, 525). No chemical means for its estimation are yet available.

Vitamin C.—This is the antiscorbutic substance which, while present in most uncooked foods, is found in exceptionally high concentration in certain fruits and in other vegetable tissues. The very fact that it is an unstable substance—easily destroyed by heat at temperatures not exceptionally high, prone to oxidation, and possibly destroyed under the influence of catalysts present in the tissues themselves—has been in itself the direct cause of much human suffering. Scurvy follows almost automatically when the substance is absent from the diet, and is often a devastating disease in communities cut off from a supply of fresh foods. The tentative efforts which have so far been made to

isolate the antiscorbutic agent, though without success, have served the useful purpose of making it clear that there is a definite substance to look for. We have not to deal with some vague 'property' of fresh foods, nor, as has been thought, with the influence of known constituents such as citrates, malates, or inorganic potassium salts. Because of its great importance to the body and the low concentration in which it is efficient the anti-scorbutic substance must certainly be recognised as a vitamin.

In the endeavour to study its distribution among foodstuffs, and the rate of its destruction by this or that agency, physiological methods have hitherto been perforce employed. For an account of methods whereby highly concentrated preparations of this vitamin are obtained and its main properties demonstrated the papers of Zilva should be consulted (*Bio-Chem. J. passim*). The discovery of even a purely empirical chemical method for estimating the vitamin would certainly be of the utmost practical importance. Determinations of its relative concentrations have been made by observing for each kind of material under study the minimal curative or preventative dose for scurvy in the guinea-pig. This animal reacts in a highly characteristic way when it is deprived of the factor in question, and also when after deprivation a supply is again provided (Axel Holst). Elaborate and careful experiments have been made on these lines (Chick and Hume, 1917, *et al.*). The vitamin is absent from dry cereal foods and from pulses, but appears suddenly in grains, beans, &c., during even the earlier stages of germination. It is present in all fresh vegetables though in varying concentrations. It is usually destroyed when these are dried, though it is stated that very rapid sun drying (an industry in Beluchistan) leaves it largely intact. Its concentration in fruits varies considerably. Those of the genus *Citrus* contain it in relatively large amount—as the long established empirical treatment of scurvy with lime juice would itself suggest. The fact that the concentration differs, however, in the juices of different varieties of citrus has affected the history of anti-scorbutic treatment. On several occasions in the past, and even during the war, 'lime juice' has appeared to fail and faith in its efficacy has consequently wavered. This occurred long ago when in the British Navy the juice of the West Indian lime was substituted for the lemon juice previously used. The explanation came when it was shown that the first-mentioned juice contained no more than one-fourth of the active substance present in the latter. Orange juice, on the other hand, contains about the same proportion as lemon juice (Chick, Hume and Skelton, *Biochem. J.* 12, 131; Davey, *ibid.* 1921, 15, 83). Orange juice retains its activity when wholly freed from its colloids and from citric acid and calcium (Harden and Zilva, *Bio-Chem. J.* 1918, 12, 259; McClendon, *J. Biol. Chem.* 1921, 46, ix.). Orange or lemon juice evaporated to a syrup under reduced pressure at 40°C. or concentrated by rapid methods at higher temperatures, retains its activity (Harden and Robison, *Bio-Chem. J.* 1920, 14, 171). The condition of the vitamin in the tomato is apparently such as to make it exceptionally stable. In all cases a slightly acid reaction in the material makes

for stability. Fresh tomato juice, for instance, boiled for one hour lost 50 p.c. of its activity; boiled for four hours it lost 70 p.c. When the juice was first made slightly alkaline, boiling destroyed it much faster (La Mer, Campbell and Sherman, *Proc. Soc. exp. Biol. and Med.* 1921, 18, 122). In the case of vegetables (cabbage) heating for twenty minutes at 100°C. may destroy 70 p.c. of the anti-scorbutic power (Delf, *Bio-Chem. J.* 1918, 12, 416). Oxidation plays a part in the destruction of this vitamin (Zilva, *Lancet*, 1921, i. 478; Anderson and others, *Science*, 1921, 53, 446). It would seem to be especially rapid in the case of some tissues. Fresh potato has marked anti-scorbutic power, but the juice, unless made acid, quickly loses it even at ordinary temperatures (Berzsonoff, *Compt. rend.* 1921, 173, 417). The anti-scorbutic value of milk, even when fresh, is relatively low, important as the function must be to the infant. The actual concentration of this vitamin (and, indeed, of the other vitamins in cows' milk) depends, however, upon the nature of the food supplied to the cow (Hess and others, *Proc. Soc. exp. Biol. and Med.* 1920, 18, 39; Drummond and others, *Bio-Chem. J.* 1921, 15, 540). The vitamin is largely destroyed by Pasteurisation, and it is becoming well recognised that infants receiving heated milk should be given a ration of fruit juice.

Vitamin A.—The 'Fat soluble' accessory factor. If animals be fed on a synthetic dietary such as that earlier described there may be complete failure of nutrition, even when Vitamins B and C are duly supplied, unless at the same time regard is paid to the nature of the fat comprised in the diet. Most vegetable fats, whether purified or not, prove unable to support nutrition in the circumstances mentioned, while most animal fats are found to be efficient, though in varying degrees. This is of course not due to any differences in the fats as fats. As a source of energy for the animal one type of fat differs but little from any other type. The difference, as abundant evidence proves, is due to the fact that associated with animal fats and not (at least as they appear on the market) with vegetable fats, is a specific substance, not itself a fat or other ester, which is essential to life. While actually made by the plant and present for instance in relative abundance in green leaves, it for some reason does not accompany vegetable oils when those are expressed from plant tissues. When, on the other hand, it is eaten by the animal in its food the substance tends to accumulate in its fatty tissues. It is stored in exceptionally large relative amounts in the livers of fish, but takes its origin from the marine vegetable organisms on which the fish feeds (Hjort, *Proc. Roy. Soc.* 1922, B). As in the case of other vitamins, its relative distribution has been in the main studied by means of standardised feeding experiments, but evidence is accumulating to show that its concentration in a fat is measured by the intensity of a colour reaction produced on the addition of arsenic chloride and certain other reagents (Rosenheim and Drummond, *Bio-Chem. J.* 1925, 19, 753). It is soluble in alcohol, ether, and benzene, and may be extracted, for example, from green leaves by these solvents. The vitamin is stable towards heat, and highly

resistant to the processes involved in saponification. It appears therefore greatly concentrated in the unsaponifiable residue from any fat which contains it. On the other hand, it is easily oxidised, and loses all activity when a fat or oil containing it is thoroughly aerated (Hopkins, Bio-Chem. J. 1920, 14, 725). Drummond and his co-workers have shown that when the unsaponifiable material from cod-liver oil is freed as far as possible from cholesterol and distilled in a high vacuum the active vitamin is found in fractions distilling at 184°-220° at pressures of 1 to 2 mm. (Bio-Chem. J. 1925, 19, 1047). An ethereal extract of green leaves has been prepared (Osborne and Mendel), of which a daily dose of 30 milligrammes contained enough of the vitamin (doubtless greatly diluted with other substances) to supply the needs of the rat, an animal highly sensitive to deprivation of the substance. Concentrations much greater than this have been obtained from the unsaponifiable residues of cod-liver oil prepared with avoidance of oxidation. Of one such preparation a daily dose of no more than 0.004 mgm. was sufficient to maintain a rat (Paulsen), and very small amounts of such concentrates will serve the purposes of the whole oil in therapeutic practice. The variation in animal fats is great. It has been estimated that cod-liver oil may be 250 times richer in the substance than butter (Zilva and Miura). For the influence of storage and emulsification on the vitamin A in cod-liver oil, see Drummond, Zilva and Coward (J. Soc. Chem. Ind. 1924, 43, 236 T).

The following figures have been obtained, representing the relative amount of the fat needed to supply a growing rat with its necessary supply of the vitamin. Crude cod-liver oil 2 mgms., haddock-liver oil 10 to 15 mgms., refined cod-liver oil on sale in this country 10 to 15 mgms., butter 500 mgms. (Zilva and Drummond, Lancet, 1921, ii. 753). The effects which follow upon an absence of this vitamin from the food, or a considerable deficiency in the supply, are failure of growth and maintenance, together with a specific form of degenerative changes in the eye, constituting what is known as xerophthalmia. It was for some time believed that the deposition of lime salts in growing cartilage on the lines necessary for the normal formation of bone called for a supply of vitamin A. The work of E. Mellanby has indeed shown clearly that something present in natural animal fats exerts an important influence on this process. When this substance is absent from its food a child becomes prone to develop rickets. It would seem, however, as McCollum and his co-workers were the first to suggest (J. Biol. Chem. 1922, 53, 293), that the dietary factor which prevents rickets, while usually associated with vitamin A, is not identical with it. It is a substance less readily oxidised. A fully aerated animal fat will fail to promote growth, but it may efficiently protect the young animal from rickets. It would seem that at least one other vitamin may therefore exist in addition to the three which have been discussed, and it is now usual to speak of this substance as Vitamin D. The remarkable relations between the activity of this food constituent and the effects of light

cannot be here discussed. It is probable that the list of existing vitamins is not exhausted by those discussed. Already there is evidence that a quite specific constituent in the diet is necessary for the maintenance of reproductive functions (Evans and Burr, Proc. Nat. Acad. Sc. 1925, 11, 334). F. G. H.

VITELLIN v. PROTEINS.

VITEXIN. The *Vitex littoralis* (A. Cunn.) or 'Puriri' is a large tree, 40-60 feet high, and 3-5 feet in diameter, which grows only in the northern portion of the North Island of New Zealand. The wood affords a very durable timber, and is chiefly used for house blocks, fencing posts, piles for bridges, railway sleepers, &c.

Vitexin, the main colouring matter, is present in the wood in the form of a glucoside which has not yet been isolated. It is prepared by digesting a purified extract of the dyestuff with boiling dilute hydrochloric acid, and by this means separates in the form of a yellow viscous mass. By extracting this crude product with boiling alcohol, a pale yellow crystalline powder remains undissolved, and this, owing to its sparing solubility, is most readily purified by acetylation, and the subsequent hydrolysis of the pure acetyl derivative (Perkin, Chem. Soc. Trans. 1898, 74, 1020).

Vitexin consists of minute canary-yellow prismatic or fine hair-like needles, soluble in alkaline solutions with a pale yellow coloration, and from these solutions when boiled it is deposited by acidification in a crystalline condition.

On fusion with alkali vitexin yields *phloroglucinol* and *p-hydroxybenzoic acid*, and when digested with boiling 50 p.c. potassium hydroxide solution *p-hydroxyacetophenone* is also produced. Boiling 15 p.c. nitric acid gives dinitro-*p*-hydroxybenzoic acid, together with a small quantity of *tetranitroapigenin*, m.p. 239°-241°. The formula first assigned to vitexin by Perkin was $C_{18}H_{14}O_8$, and the *acetyl derivative*, colourless prismatic needles, m.p. 251°-256°, was consequently represented as $C_{18}H_{12}O_7(C_2H_3O)_2$. In a later communication in view of its apparent relationship to apigenin, and the difficulty of accounting for the large number of hydroxyl groups which are present, it is suggested by this author (Chem. Soc. Trans. 1899, 77, 422) that vitexin is probably a very stable glucoside of apigenin represented by the formula $C_{15}H_{10}O_6$. Vitexin is a somewhat feeble colouring matter, and dyes shades similar to those given by apigenin; these, employing woollen cloth mordanted with chromium, aluminium, and tin, are respectively greenish-yellow, pale bright yellow, and pale brown.

In addition to vitexin the wood of the *Vitex littoralis* contains (as glucoside) a small quantity of a second colouring matter, *homovitexin*. It was obtained as a pale yellow powder, m.p. 245°-246°, and is distinguished from vitexin by its ready solubility in alcohol. Fused with alkali it gives *phloroglucinol* and *p-hydroxybenzoic acid*, and is possessed of feeble dyeing property. The analytical figures approximate to $C_{15}H_{10}O_6$ or $C_{18}H_{12}O_8$.

According to Barger (Chem. Soc. Trans. 1906, 89, 1120) the glucoside saponarin, which is present in *Sapponaria officinalis* (Linn.), yields on hydrolysis glucose, saponaretin and a small

quantity of vitexin. It is possible that saponarin and homovitexin are identical. A. G. P.

VITRIFIABLE PIGMENTS v. POTTERY; also PORCELAIN.

VITRIOL (*vitrum*, 'glass'). An old name for a sulphate, and still frequently applied to the sulphates of certain common metals on account of their vitreous lustre, e.g. white or zinc vitriol $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$; blue or copper vitriol $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$; green or iron vitriol $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$; red or cobalt vitriol $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$. Basic ferric or ferroso-cupric sulphates obtained in the extraction of copper sulphate from ferruginous minerals are known as Admont, Bayreuth, Salzburg vitriols, &c.

VITRIOL, OIL OF. *Vitriolic acid*. Sulphuric acid (*q.v.*).

VITRIOL STONE and **COLCOTHAR**. Vitriol is the material from which the so-called fuming or Bohemian sulphuric acid was formerly manufactured, and it is obtained from the rock known as vitriol slate ('Vitriolschiefer') in the following manner. Large masses of pyritous slate (which belongs to the Silurian formation, and consists of a quartzose matrix containing pyrites, carbon, and clay) are exposed to the weathering action of the atmosphere for three years. The products of oxidation so formed are ferrous sulphate and sulphuric acid, which latter acts upon the clay, yielding aluminium sulphate and other sulphates. The ferrous sulphate at first formed becomes by oxidation ferric sulphate, which, together with the aluminium sulphate, is the principal product of the weathering of the vitriol slate. Ferrous sulphate remains only in small quantities. The next operation is lixiviation of the mass with water, after which the liquor obtained is concentrated to a density of 40°B. , and finally evaporated in pans until, on cooling, a crystalline cake of vitriol stone is obtained. The vitriol stone is now calcined, in order to remove the greater part of its water. The resulting product, when heated to a high temperature in clay retorts, yields sulphur trioxide; and a residue, termed *colcothar*, remains in the retorts. The composition of vitriol stone and colcothar may be seen from the following analyses:—

Vitriol stone.— Fe_2O_3 , 20.07, Al_2O_3 , 4.76, FeO 0.64, MnO traces, CaO 0.14, MgO 0.39, K_2O 0.07, Na_2O 0.05, CuO 0.10, SiO_2 0.10, P_2O_5 traces, SO_2 40.51, As traces, H_2O 32.58. Total 99.32; or combining acid oxides and bases: $\text{Fe}_2(\text{SO}_4)_3$, 50.17, $\text{Al}_2(\text{SO}_4)_3$, 11.94, FeSO_4 , 1.35, MgSO_4 , 1.17, CaSO_4 , 0.33, CuSO_4 , 0.20, K_2SO_4 , 0.13, Na_2SO_4 , 0.11, H_2SO_4 , 1.49, MnO , As , and P_2O_5 traces, SiO_2 0.10, H_2O 3.31—99.29.

Colcothar.— Fe_2O_3 , 7.62, Al_2O_3 , 12.53, MgO 3.23, CaO 0.82, SO_2 , 5.17, SiO_2 , 1.17, CuO 0.20, H_2O 1.30—99.04 (F. Stolba, B. Königl. Böhm. Gesells. 1885; J. Soc. Chem. Ind. 6, 30).

VIVIANITE. Hydrated ferrous phosphate $\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, crystallised in the monoclinic system. The crystals have a perfect cleavage in one direction, parallel to the plane of symmetry; they are quite soft ($\text{H. } 1\frac{1}{2}$), sectile, and easily bent, being flexible but not elastic. Sp.gr. 2.58–2.68. Crystals from freshly opened rock

cavities are colourless, but on exposure to the air they very soon acquire a greenish-blue tinge, darkening to a characteristic deep indigo-blue. This change in colour is due to a partial oxidation of the iron, which in the black kertschenite $(\text{Fe,Mn,Mg})\text{Fe}^{++}(\text{PO}_4)_2 \cdot 7\text{H}_2\text{O}$, from the Kerch peninsula, Crimea, is almost complete. Vivianite is the commonest of the several iron phosphate minerals. The best crystals are found in metalliferous veins, e.g. at Wheal Jane, in Cornwall, with pyrrhotite, and at Leadville in Colorado. Crystals are also found in the interior of fossil shells, e.g. in the iron ores of the Kerch peninsula, Crimea; and also sometimes in bones and horns buried in peat deposits. More often the mineral has the form of a blue earthy powder ('blue iron-earth'), and it is in this form that phosphorus is present in bog iron-ore and other limonitic ores of iron. L. J. S.

VOLBORTHITE. Hydrated basic copper vanadate $(\text{CuOH})_2\text{VO}_4 \cdot 6\text{H}_2\text{O}$, with the copper in part replaced by calcium, barium, and magnesium. It forms olive-green or citron-yellow, pearly scales, which are often aggregated in globular forms. As a dissemination in sandstones of Permian age it occurs over a wide area in Govt. Perm in Russia.

Calciovolborthite is a mineral of very similar appearance and mode of occurrence. It contains, as a rule, rather more calcium and has no water of crystallisation; the composition approximates to the formula $\text{Cu}_2(\text{CuOH})_2(\text{VO}_4)_2$. This is found as golden-yellow or greenish-yellow pearly scales and rosettes on the surfaces of sandstone in Utah, Colorado, and Oregon, and also at Friedrichroda, near Gotha, in Thuringia. On the significance of these occurrences of vanadium and copper minerals in sandstones v. PSITTACINITE. L. J. S.

VOLCANIC GLASS v. OBSIDIAN.

VOLCANIC TUFF v. TUFF.

VOLEMITOL v. CARBOHYDRATES.

VOLUMENOMETER v. SPECIFIC GRAVITY.

VOROBYEVITE v. BERYL.

VRAIC. *Varech*. The French name for kelp, v. IODINE.

VRBAITE. Thallium sulph-arsenite and antimonite $\text{TlAs}_2\text{SbS}_5$ or $\text{Tl}_2\text{S}_2\text{As}_2\text{S}_5\text{Sb}_2\text{S}_5$, containing Tl 32.15 p.c., crystallised in the orthorhombic system. It is greyish-black with metallic lustre, but in thin splinters dark red, and the powder is light red with a yellowish tinge. Sp.gr. 5.3. The small crystals are found embedded in realgar and orpiment, at Allichar, in Macedonia. Another mineral containing thallium as an essential constituent yielded by this locality is lorandite (*q.v.*). L. J. S.

VULCANISED OILS v. OILS, FIXED, and FATS.

VULCANITE v. RUBBER. Also applied to a nitroglycerin explosive.

VULCAN POWDER v. EXPLOSIVES.

VULPIC or **VULPULIC ACID** v. LICHENS.

VULPINITE. A variety of anhydrite mixed with silica. That from Vulpino near Bergamo, known as the *Marmo Bardiglio di Bergamo*, takes a fine polish and is used for ornamental purposes.

W

WAD or **BOG-MANGANESE**. A black, earthy mineral consisting mainly of hydrated manganese dioxide, but of variable composition, barium and various other constituents being often present. Many varieties have consequently been distinguished by special names. *Asbolite* or 'earthy cobalt' is a cobaltiferous variety, and *lampadite* contains copper. The mineral may be regarded as an earthy form of psilomelane (*q.v.*); it is so soft and sooty that it soils the fingers, and is sometimes so porous that it floats on water. It has resulted from the weathering and decomposition of other manganese minerals, and is sometimes deposited from solution by springs and in swamps. It is of wide distribution and is mined at many places together with other oxides of manganese. *Asbolite* is of importance as an ore of cobalt (up to 35 p.c. CoO), as much as 5000 tons per annum having been exported from New Caledonia. L. J. S.

WALNUT HUSKS (*Brous des noix*. Fr.) are employed by the French dyers to give dun colours. The green shells contain *juglone* or *hydroxy-[α]-naphthaquinone*; *v. NAPHTHALENE*.

WALNUT OIL *v. OILS, FIXED, AND FATS*. Walnut oil is obtained from kernels of the walnut tree (*Juglans regia*), which contain from about 65 to 66 p.c. of oil. The best oil is separated by cold expression and from its pale colour is a favourite medium for white paints, and is commonly termed 'nut oil' by artists. It dries more slowly than linseed oil, but yields a more elastic film. In the bromination test it yields from 1.5 to 2 p.c. of an insoluble bromide, which appears to be that of a mixed glyceride.

An oil of similar character is obtained from the seed of the North American walnut, *Juglans niger*. This oil is termed *pecan oil*.

The fruit of *Juglans Siboldiana* gave 26.54 p.c. of kernel, which contained 4.99 p.c. of water, and gave 59.58 p.c. of oil by pressing. The oil has a light yellow colour and no odour, and has the following characters: sp.gr. 0.9332 at 15°; $n_D^{20} = 1.4800$; acid value 0.68; Hehner value 92.3; saponification value 191.1; Reichert-Meißl value 0.62; and iodine value (Hübl.) 150.8, and has the properties of a drying oil. C. A. M.

WALSRODE POWDER *v. EXPLOSIVES*.

WARAS, also called 'wars' and 'wurrus,' consists of a purplish resinous powder which covers the seed pods of *Flemingia congesta* (Roxb.), an erect woody shrub growing in the thickets and forests of the warmer parts of India. According to Watt (Dictionary of Economic Products in India, iii. 482), it is collected also in Africa in the neighbourhood of Harrar, and is sent to Arabia, chiefly to Yemen and Haddramant, where it is used as a dye, as a cosmetic, and as a specific against colds. According to Wardle, waras is distinctly inferior as a dye to kamala, which it closely resembles, and contains only a small amount of colouring matter compared with the yellow vegetable dyes of commerce. It is suitable as a dye for silk rather than for wool, but is quite useless with cotton. It has been

introduced into England from Aden as an adulterant or substitute for kamala (Flückiger and Hanbury's Pharmacographica, 1879, 576). Under the microscope waras appears as orange-brown lumps, frequently circular and closely resembling kamala.

Flemingin $C_{13}H_{12}O_4$ (provisional) is a dull orange-red crystalline powder consisting of star-shaped groups of minute prismatic needles, which melt at 171°–172°, and closely resembles the rottlerin of kamala. Solutions of the alkali hydroxides dissolve it with an orange-brown tint, but these solutions when boiled do not deposit resinous matter, as is the case with rottlerin. On fusion with alkali *salicylic acid* and acetic acid are produced.

Silk suspended in a solution of *flemingin* in dilute sodium carbonate, and the whole gradually raised to the boiling temperature, is dyed golden yellow, slightly duller than the shade given by rottlerin; but, on the other hand, *flemingin* possesses much the stronger dyeing power of the two.

In addition to *flemingin* waras contains a trace of a yellow crystalline colouring matter, *homoflemingin*, m.p. 165°–166° ($C = 69.97$; $H = 5.75$), together with some quantity of two resinous substances: (a) $C_{12}H_{12}O_3$ (?), m.p. 162°–167°, and (b) $C_{13}H_{14}O_3$ (?), melting below 100°. Fused with alkali these latter gave *salicylic* and *acetic acids*, and appear to be allied to *flemingin*.

Added to a boiling solution of its own weight of sodium carbonate, waras dyes silk golden yellow shades, which are brightened by rinsing in very dilute acetic acid. Contrary to the statement of Wardle, it is to be regarded as a decidedly superior dyestuff to kamala (Perkin, Chem. Soc. Trans. 1898, 73, 659). A. G. P.

WASH. The name given to the fermented wort of the distiller.

WATER.

ITS PHYSICAL AND CHEMICAL PROPERTIES.

Purification.—Because of its solvent action on solids and gases, water is difficult to purify and still more difficult to keep in a pure state. It may be partially freed from dissolved salts by freezing, the ice separating from any unsaturated salt solution containing only the small quantity of the dissolved salt present in the mother liquor included in the ice crystals. The ice separating from, say, sea-water, is fairly free from saline matter. It is not known whether this method of purification eliminates, partially or completely, dissolved gaseous impurities. The method is relatively troublesome and costly, and has not been practically applied.

Water is commonly purified by distillation under atmospheric pressure. When adequate arrangements are made to prevent carrying over of entrained droplets of water formed upon the bursting of steam bubbles, the condensed steam contains only the solid and gaseous impurities it dissolves after condensation. Assuming dust to be excluded, the non-volatile impurities in the distillate will be confined to such traces of

lime, silica, alkalis, tin oxide, etc., as may be derived from condensers and containers, and the volatile impurities, which generally are much the more serious in amount and effect, will comprise volatile organic matter, ammonia, carbon dioxide, oxygen, nitrogen, and the like, originally contained in the raw water and carried over with the steam or dissolved from the atmosphere with which the condensate is in contact.

The proportion of non-volatile impurities may be reduced to insignificance by using suitable material for condensers and containers. Hot, newly condensed water has a much greater solvent action than when cold; therefore a material suitable to contain water for a given purpose may not serve for its condensation. Good resistance glass vessels, which have been freed from superficial soluble matter by blowing steam into them for some hours in such a way that the condensate drains away continuously, after long standing in cold water will yield little impurity to pure water during several weeks. Such glass, so treated, is suitable for the preservation for short periods of cold pure water for all but a few very special purposes. It is unsuitable for condensers, which are usually made of pure block tin or heavily tinned copper. The risk of introducing non-volatile impurity may be reduced by using pure fused silica, or, better, pure tin or silver as the material of condenser and receiver. Occasionally water has been condensed and kept in vessels of gold or platinum, but for all ordinary and most special purposes water condensed in pure tin and kept a short time in steamed resistance glass is quite satisfactory. Water kept in ordinary glass bottles for some weeks or months may dissolve sufficient silica, &c., from the glass to render it unsuitable for ordinary precise analytical work, especially that in which small amounts of silica must be determined.

In the estimation of ammonia in water and for work upon conductivity of dilute solutions, the volatile impurities are much the more serious. Fortunately simple precautions suffice to eliminate them. Organic matter may be destroyed by adding to the raw water in the still a small proportion of potassium permanganate or manganate, with sufficient caustic soda or potash to make the water distinctly alkaline (Stas, *Mém. Acad. Belg.* 1865, 35, 1; *Chem. News*, 1861, 4, 207; 1867, 15, 204). Practically the whole of the carbon dioxide and ammonia will come over with the first 20-30 p.c. of the distillate, and if this be rejected the remaining two-thirds will be pure water.

Many procedures have been described, in which the acidic and basic impurities are retained in the still by added reagents, e.g. aluminium sulphate, potassium hydrogen sulphate or phosphoric acid to retain ammonia, or lime or baryta to retain carbon dioxide (see, e.g. Hulett, *Zeitsch. physikal. Chem.* 1896, 21, 297; Walker and Cormack, *J. Chem. Soc.* 1902, 77, 5; W. R. Bousfield, *ibid.* 1905, 87, 740; 1912, 101, 1443). Some workers have obtained fair conductivity water by redistillation of laboratory distilled water without added reagents (see Bousfield, *loc. cit.*; Hartley, Campbell and Poole, *J. Chem. Soc.* 1908, 93, 428; Thole, *ibid.* 1912, 101, 207).

In a simpler method for the positive chemical elimination of basic and acidic impurities in one operation, a large glass flask containing an aqueous solution of 10 p.c. potassium dichromate and 5 p.c. sulphuric acid is heated, raw water is run in at a rate equal to the rate of evaporation, and the steam is led through a second flask, also heated, containing saturated baryta solution and then condensed in tin (Moseley and Myer, *J. Amer. Chem. Soc.* 1918, 40, 1409: this method was partially employed by Paul, *Zeitsch. Elektrochem.* 1914, 20, 179).

But still simpler methods are effective. It has long been known that ordinary 'conductivity' water, having a conductivity about 1.0×10^{-6} mho (1 gemmho) is materially improved by contact with an atmosphere freed from carbon dioxide, e.g. by enclosure over lime or even by passing through it clean air from the open, whilst it deteriorates markedly in contact with air contaminated by human breath or by flames (Kohlrausch, *Zeitsch. physikal. Chem.* 1902, 42, 193).

If a current of purified air be passed through such water heated nearly to its boiling-point in a quartz still, and the water distilling under these conditions be condensed in block tin and collected in quartz, it has a conductivity of $0.05-0.07 \times 10^{-6}$ mho at 18° (Weiland, *J. Amer. Chem. Soc.* 1918, 40, 131). Such water compares favourably with the purest conductivity water prepared by distilling repeatedly *in vacuo* in sealed glass vessels and had a conductivity of 0.043×10^{-6} mhos at 18° (Kohlrausch and Heydweiller, *Zeitsch. physikal. Chem.* 1894, 14, 317; Kohlrausch, *Proc. Roy. Soc.* 1903, 71, 338). This method is applicable only to those cases where carbon dioxide is the sole impurity, but the same principles have been applied in a method, applicable to all types of water, first described by Bourdillon (*J. Chem. Soc.* 1913, 103, 791) and elaborated by Clevenger (*J. Ind. Eng. Chem.* 1919, 11, 964). Raw water containing potassium bisulphate or phosphoric acid is distilled, and the steam is carefully scrubbed and separated from spray and led into a long vertical tube through which a current of purified air passes from the bottom upward. The upper end of this tube is surrounded by a water-jacket maintained nearly at 100°, which, therefore, condenses, but does not cool, the major portion of the steam; the uncondensed steam escapes either to the air or to a second condenser. The hot condensate which flows down the walls of the tube in contact with pure air, is cooled by a cold-water jacket surrounding the lower part of the tube and passes away by a syphon. The apparatus is best constructed wholly of copper heavily tinned and soldered with pure tin. Thus it is not difficult to prepare water having a conductivity about 0.05×10^{-6} mho, but it cannot be preserved save under rigid exclusion of atmospheric carbon dioxide. In contact with clean air its conductivity increases to a limiting value of about 0.75×10^{-6} mho, which is that of a solution of carbonic acid in equilibrium with the $0.035 (\pm 0.004)$ volume p.c. of carbon dioxide present in air (Kendall, *J. Amer. Chem. Soc.* 1916, 38, 1490). Kendall has suggested that as such a solution is permanent it is preferable to use it and correct for its

known conductivity rather than to use water of lower conductivity, the correction for which must be uncertain (Kendall, J. Amer. Chem. Soc. 1916, 38, 2480; *g.v.* also for a full discussion and bibliography of previous work on the preparation of conductivity water).

Pure water has been prepared in other ways. Baker found that pure water prepared by the union of pure and dry hydrogen and oxygen differs in some respects from ordinary pure water. If steam from pure water be passed through a red-hot silica tube and then condensed in silica and Jena glass, the condensate acts upon pure 1 p.c. sodium amalgam much more slowly than do other types of water. This inactivity is independent of the conductivity of the water, and there is evidence that it is due to the absence from such water of traces of hydrogen peroxide which constitute a normal impurity in ordinary pure water (Baker and Parker, J. Chem. Soc. 1913, 103, 2060; Parker, *ibid.* 2071).

Pure water may also be prepared by dehydrating pure hydrates, *e.g.* hydrated barium chloride or telluric acid, H_2TeO_4 , by heat; but the method has usually been applied to obtain very small, accurately known, amounts of water in closed apparatus, and little or nothing is known of the properties of such water.

THE RELATION OF PRESSURE AND TEMPERATURE FOR STEAM, WATER, AND ICE.

The pressure, temperature, volume, and state of aggregation of water are, of course, interdependent, and it is thus difficult to discuss separately the effect of variation of any one or two of these factors. Possibly the simplest method is to discuss first the relations of pressure and temperature for the various states of aggregation, and then consider the effect upon volume of varying temperature and pressure considered separately.

Fig. 1 is the complete pressure-temperature diagram for water, except that to save space the steam-line ΔJ is not continued to the critical point at which it terminates, viz. 374°C. and 217 atmo. The diagram is defective also in that the line ΔLM stands for the vapour-pressure curves of both ice and supercooled water, which are in fact distinct but by an amount entirely inappreciable on the scale of pressure necessarily adopted. The line ΔL represents the vapour pressure of supercooled water, which has been measured down to -16.3° and is given in Table 1; the line ΔM shows the vapour pressure of ice which has been measured down to about -70° , and is given in Table 2 from -80° to 0° . The maximum difference between the vapour pressures of ice and supercooled water is 0.200 mm. at -11.7° .

The vapour pressure of water has been the subject of much accurate experimental work. The data given in Table 3 from 0° – 100° and in Table 4 from 100° – 370° , and represented on the diagram by the line ΔJ , are the values regarded as most probable.

The area below the line ΔJ represents the vapour phase, and water as we know it at or near atmospheric pressure, is, on the scale of Fig. 1, represented by little more than the thickness of that line.

For many purposes the changes in the boiling-point of water attending small changes of pressure are of great practical importance. At pressures in the neighbourhood of 1 atmo. the value of dt/dp for $dp=1$ mm. of mercury is 0.0376° (Wiebe, *Zeitsch. für Instrumentkunde*, 1893, 13, 329); and the precise values of the boiling-point of water at pressures from 720–800 mm. of mercury are given in a form convenient for reference in Table 5.

Our knowledge of the rest of the PT diagram, covering a range of temperature from -80° to $+80^\circ$ at pressures from 1 to over 20,000 kgm./cm.^2 , rests upon the work of Tamman as confirmed and extended by Bridgman. The principal numerical data are given in Tables 6 and 7, which show respectively the variations in the melting-points and transition-points of the various forms of ice with variation in pressure; their significance is evident from a consideration of Fig. 1. The line ΔB represents the equilibrium between water and ordinary ice, Ice I. At pressures above about 2000 kgm./cm.^2 , whatever the temperature, Ice I cannot exist, but changes into one of the denser forms of ice, II or III, the equilibria between which and Ice I are represented respectively by $\kappa'GB$ and κGB . The line $\kappa'G$ represents stable equilibrium between Ice I and Ice II, whereas κG is the locus of equilibrium between Ice I and Ice III in a metastable condition. Ice III has a stable existence only in the range of temperature and pressure denoted by the area $BCFG$, within which are smaller areas (shown on a larger scale in the upper part of Fig. 1) in which labile modifications of Ice I and Ice III, called respectively Ice I' and Ice III', can exist. The inter-relation of these forms is not as yet well understood.

Two other still denser forms of ice exist at higher pressures. Ice V is in equilibrium with Ice III at about 3500 kgm./cm.^2 over a small range of temperature in the neighbourhood of -20° ; its equilibrium with Ice II has been followed over a small range only, the point x being conjectural. The stable equilibrium between Ice V and water, indicated by the line CD , has been traced some distance into the area of Ice III as shown, Ice V being here metastable. Above a pressure of about 8500–8000 kgm./cm.^2 Ice V and Ice II are converted into Ice VI, the only form observed at higher pressures. Its equilibrium with liquid water is represented by the line DH , and it is remarkable that at the highest pressures this form is stable at temperatures up to 75° . The existence of metastable Ice VI in equilibrium with liquid water has been traced along the line DD' for a considerable distance in the area of Ice V. The estimated densities of the different forms of ice are:—Ice II 1.03; Ice III 1.04; Ice V 1.06; Ice VI 1.09; as compared with ordinary ice 0.92 and water=1.00.

It must be understood that the evidence for the separate existence of these solids is simply the abrupt change of volume, manifested by a sudden drop of pressure, observed in a mass of water subject to isothermal compression. The conclusion that these are solid forms of water is supported by the fact that Ice III formed at about 2500 kgm./cm.^2 and -20° to -30° , if cooled first to -80° and then

to -190° , is so stabilised that it is unchanged on release of pressure and can be examined in the open. At temperatures of -120° or higher under atmospheric pressure, the clear trans-

parent Ice III breaks down into a bulky powder of Ice I (Tammann, *Zeitsch. anorg. Chem.* 1909, 63, 285; *Zeitsch. physikal. Chem.* 1910, 72, 609; 1913, 84, 257).

Fig. 1.

The extent and direction of the line DH are of great theoretical interest, inasmuch as they lend no support to the hypotheses which have been formulated (Poynting, *Phil. Mag.* 1881, [5], 12, 32; Ostwald, *Lehrbuch der allgemeinen Chemie*, 1902, 2, ii. 373, 391; Tammann, *Kristallisieren und Schmelzen*, Leipzig, 1903, 29; Planck, *Wied. Ann.* 1882, 15, 446) that the melting-point curve of a solid should, with increase of pressure, terminate at a critical end-point analogous to that of the boiling-point curve, or pass through a maximum.

Critical data for water have been determined as follows:

Authority	Crit. temp.	Crit. press.	Crit. vol.	Crit. density
1	358.1°	—	0.001874	0.429
2	364.3°	194.6 atm.	0.003864	—
3	374.0°	217.0 atm.	—	—

THE RELATION OF VOLUME AND TEMPERATURE AT MODERATE PRESSURES FOR STEAM, WATER, AND ICE.

It is convenient next to consider the relation of the volume of unit mass of water to tem-

perature at ordinary or moderate pressures, and the available data are presented in a further series of tables. Table 8 shows the specific volume in c.c. per gram of saturated water vapour corresponding to each degree of temperature from 0°-180°; the specific volume of

TABLE 8.
SPECIFIC VOLUME OF SATURATED WATER VAPOUR.

In cubic centimetres per gram, at temperatures on the constant volume gas-thermometer (Reichsanstalt) scale.

Tempera- ture. Tens of degrees	Degrees

180	195.1	—	—	—	—	—	—	—	—	—

Calculated by Holborn, Scheel and Henning (Wärmetabellen, 1919) from the results of Holborn and Henning (Ann. Physik. 1908, [iv.] 26, 833) and Henning (ibid. 1906, [iv.] 21, 849; 1909, [iv.] 29, 441). See also J. Southern, Phil. Mag. 1903, 17, 120.

superheated steam is similarly given at 10° intervals of temperature and for pressures from 1-19 kgm./cm.² in Table 9.

The specific volume is given for super-cooled water from -13° to 0° in Table 10, and for stable water from 0°-35° by tenths of a

degree in Table 12, from 30°-100° by degrees in Table 14, and, under pressure of the saturated vapour for ten-degree intervals, from 100°-320° in Table 15. For convenience, the same data in terms of specific gravity are given also in Tables 10, 11, 13 and 15.

8. Barnes, Phys. Zeit. 1901, 3, 81; Barnes and Cooke, Trans. Roy. Soc. Canada, 1902, 8, (iii.), 143.

9. Vincent, Proc. Roy. Soc., 1902, 69, 422.

A large number of formulae, for the most part entirely empirical, have been proposed to express the variation of volume of water with temperature, and these are collected, e.g. in Landolt-Börnstein Tabellen, 1921, p. 1231.

As examples the following may be given for water from 0°–40° and from 17°–100° respectively, due to Thiesen, Scheel and Dieckelhorst (Abh. Phys.-Tech. Reichsanstalt, 1900, 3, 1) and Thiesen (Wiss. Abh. Phys.-Tech. Reichsanstalt, 1903, 4, 1). If s = the density,

$$1 - s = \frac{(t - 3.98)^2}{503570} \times \frac{t + 283}{t + 67.26} \quad (\text{from } 0^\circ - 40^\circ)$$

$$1 - s = \frac{(t - 3.982)^2}{466700} \times \frac{t + 273}{t + 67} \times \frac{350 - t}{365 - t} \quad (\text{from } 17^\circ - 100^\circ)$$

These volume changes may also be considered in terms of the coefficient of cubical expansion α ,

which varies with temperature in the general manner indicated below:

Temp.	20°	40°	60°	100°	140°	180°	200°
$\alpha \times 10^6$	110	217	305	452	584	722	788

(See Meyer, Nernst's Festschrift, Halle a. S., 1912, 278; Hirn, Ann. Chim. 1866, [iv.] 10, 32; Tammann and Zepernik, Zeitsch. physikal. Chem. 1895, 16, 659.)

Despite many investigations our knowledge of the density and expansion of ice is not entirely satisfactory. Table 16 gives an indication of the methods adopted, the kinds of ice used, and the final results obtained in the chief researches on the subject; the papers by Barnes and Cooke and by Vincent, cited in the Table, contain critical reviews of earlier work and should be consulted for more detailed information.

Upon examination it is at once apparent

that these data differ among themselves by amounts much greater than any experimental error to which the actual determination of density can conceivably be subject.

With isolated exceptions the values for natural ice approximate to 0.918, whilst those for artificial ice are near 0.916. The mean values in the Table are respectively less than and greater than these figures, because they each include exceptional data which appear from their magnitude to belong to the other classification. Nichols first drew attention to this apparently systematic difference, and his experiments seem to show firstly, that it is real, and secondly, that the density of natural ice decreases with lapse of time until it approaches that of artificial ice. The experiments of Barnes and Cooke, made with natural ice from the St. Lawrence river, which had been in storage for various periods up to three years, confirm the correctness of the lower value for old natural ice, but it seems probable that none of their samples of ice were as recently formed as those which other observers had found of high density, and their conclusion that age has no effect on the density of ice is open to doubt.

Cooke (Trans. Roy. Soc. Canada, 1902, 8 [iii.] 127), in a discussion of these and earlier results, advances the view that the differences arise from stresses produced in the mass of ice by certain modes of freezing, but it is evident that Nichols' results with icicles discount this hypothesis. Vincent, measuring directly the upward pull exerted by a mass of water or ice completely immersed in mercury, confirmed generally the lower value for artificial ice, but obtained very definite evidence that the same specimen of water can, on different occasions, freeze into specimens of ice having distinctly different densities.

Further investigation is clearly needed on this point, and in the meantime the density of ice may perhaps best be taken at the mean value of 0.917.

Leduc has attempted to show that the observed differences may be due to variation in the content of dissolved air, but this explanation seems inadequate, especially in view of Vincent's results; he finds ice prepared by repeatedly freezing *in vacuo* water previously boiled to expel gases has a density of 0.9176 (Compt. rend. 1906, 142, 149).

The difference between the density at 0° of water, 0.99987, and ice, 0.917, nearly 13 p.c.,

is a measure of the great expansion which takes place when water is frozen. Many important practical consequences of this expansion are well known. Freezing water produces disruptive effects in the cells of plant and animal tissues and in pipes and containers of all sorts, and these effects, occurring in the crevices of rocks, stones and buildings, and of the soil, cause progressive superficial disintegration. When water is cooled by contact with cold air, ice is formed, and because of its lower density remains, on the surface; the temperature of the bulk of water does not fall below 4°C., the temperature of maximum density, at which cooling by convection ceases. When water in process of cooling is continuously mixed, as in running streams, and free radiation occurs from the bed-rock to a clear atmosphere through shallow water, the temperature of the bed-rock and the water in contact with it may fall below 0°, when the so-called 'ground,' 'anchor' or 'frazil' ice is formed at the bottom.

Freezing of Water in Capillary Systems.—Much of the water of soils and inorganic gels fails to freeze, even at temperatures as low as -78°, because it is physically adsorbed, chemically combined, or in solid solution. E. A. Fisher (J. Physical Chem. 1924, 28, 360) points out that water present in very fine capillary tubes or pores must be under considerable tension, and so the density may not necessarily be the same as that of water in bulk, but probably less. Hence the expansion on freezing will probably be less, and since the amount of water which fails to freeze is determined by dilatometric measurements, false conclusions may thus be drawn (Chem. Soc. Abstr. 1924, 126, ii, 391).

Temperature of Maximum Density.—The data given in Tables 11 and 12 show the well-known fact that water attains a maximum density at about 4°C. Precise investigation has fixed the temperature as 3.98° at atmospheric pressure (Chappuis, Wied. Ann. 1897, 63, 202; Thiesen, Scheel and Diesselhorst, Wiss. Abh. Phys.-Tech. Reichsanstalt, 1900, 3, 68; de Coppet, Ann. Chim. 1903, [vii.] 28, 145).

At higher pressures the temperature of maximum density of water falls progressively in the manner shown in Table 17, and expressed in the following formula (Lussana, Nuovo Cim. 1910, [v.] 19, 182)

$$t_m = 4.10 - 0.0225(p-1)$$

TABLE 17.

VARIATION OF THE TEMPERATURE OF MAXIMUM DENSITY OF WATER WITH PRESSURE.

Pressure.	Temperature of Maximum Density.	
1 atmo.	4.08°	Grassi, Ann. Chim. 1851, [iii.] 31, 437.
1.75 "	4.0	
2.85 "	3.9	
4.06 "	3.8	
5.5 "	3.7	
6.9 "	3.6	
8.6 "	3.5	
10.5 "	3.4	
41.6 "	3.3	Amagat, Compt. rend. 1903, 116, 946.
99.3 "	2.0	
144.6 "	0.6	

For this reason in specifying water at its temperature of maximum density as the standard of density, it is necessary to stipulate that the pressure must be normal. It is also lowered by the presence of dissolved salts. For a given salt, the lowering is proportional to the concentration of the solute (Law of Despretz, *Ann. Chim.* 1839, [ii.] 70, 49; 1840, [ii.] 73, 296), but it is not connected with the depression of the freezing-point and is not a colligative property (Rosetti, *Ann. Chim.* 1867, [iv.] 10, 461; 1869, [iv.] 17, 370). The molecular lowering of the temperature of maximum density by salts of monovalent ions (e.g. H⁺, Li⁺, Na⁺, K⁺ and NH₄⁺ with Cl⁻, Br⁻, I⁻ and NO₃⁻) does exhibit a regularity in that it can be calculated from the molecular lowering of HCl (the lowest) by adding two numbers, characteristic respectively of the particular base and acid present (Wright, *J. Chem. Soc.* 1919, 115, 119): weak acids, and the salts of divalent acid and basic radicles, show no such regularity (de Coppet, *Ann. Chim.* 1894, [vii.] 3, 246, 268; *Compt. rend.* 1897, 125, 533; 1899, 128, 1559; 1900, 131, 178; 1901, 132, 1218; 1902, 134, 1208).

THE RELATION OF VOLUME AND PRESSURE FOR WATER AND ICE.

The effect of large variations of pressure upon the volume of water or ice is usually expressed in terms of the compressibility coefficient β where

$$\beta = \frac{1}{V_1} \times \frac{V_1 - V_2}{p_2 - p_1}$$

where V_1 = the volume at an initial pressure p_1 ,

and V_2 the volume at a higher pressure p_2 , at the same temperature; β is evidently the fraction by which the original volume is reduced for unit increase of pressure.

Table 18 gives the values of $\beta \times 10^6$ for water according to Amagat for pressures from 1-3000 atmospheres and temperatures from 0°-200°C. Table 19 gives the results, more accurately, but relating to a much smaller range of temperature and pressure, obtained by Richards and Stull and by Tyrer, and, for comparison, those of Bridgman at 0° and 22°.

The same data can, of course, be expressed in terms of specific volume, and Table 20 gives this quantity for water over a range of pressure from 0-12,000 kgm./cm.² and from -20° to +80°C.

Normal liquids show a compressibility which decreases with rise of pressure and increases with rise of temperature. These data show that the compressibility of water is thus affected by rise of pressure, but that increase of temperature up to about 50° lowers the compressibility; at higher temperatures the compressibility of water increases with rise of temperature like that of other liquids. The significance of this fact in relation to current hypotheses of the constitution of water is discussed elsewhere. The relation of the coefficient of expansion of water to pressure and temperature is given in Table 21. Experiments upon the isopiestic expansion of water at higher temperatures and pressures show that the thermal expansibility increases with temperature to a maximum value which is the less the greater the pressure (Watson, *Proc. Roy. Soc. Edin.* 1911, 31, 456).

P. W. Bridgman, Proc. Amer. Acad. 1912, 48, 338.

Increase of pressure does not shift the temperature of minimum compressibility, but at high pressures this minimum disappears (Bridgman, Zettech. anorg. Chem. 1912, 77, 377).

Small as is the compressibility of water it has important practical effects and uses. It has been calculated that were water incompressible the mean sea-level would be 116 feet higher than it actually is, whereby about 4 p.c. of existing

land would be submerged (Tait, Proc. Roy. Soc. Edin. 1884, 12, 46; 1892, 20, 63, 141). Compression waves in water are transmitted with high velocity and are applied in the Constantinesco 'wave-power' system to attain the economical transmission of power, e.g. from a central motor to drilling machines or the like in mines, with an efficiency comparable with that of electrical transmission and with the

TABLE 21.

Amagat, Compt. rend. 1887, 105, 1120.

convenience and safety characteristic of compressed air.

The compressibility of ice at -7.03° for a range of pressure from 100-500 megabars is 0.0000120 (Richards and Speyers, J. Amer. Chem. Soc. 1914, 36, 491), or about one quarter that of water at 0° ; it does not decrease greatly with increase of pressure. The much higher value calculated by Bridgman (0.000036) probably indicates that the temperature coefficient of increase of compressibility for ice is abnormally high.

In considering the remaining physical properties of water it is convenient to take them in a systematic order for all forms of water, under the main groups, mechanical, thermal, optical and magnetic, and electrical.

MECHANICAL PROPERTIES.

Crystal Form.—Ice crystals, as exemplified by snow, can assume a great variety of forms which are commonly characterised by extreme openness of structure and consequent lightness; they are readily formed by the condensation of water vapour below 0° as hoar frost. Liquid water, if free from dissolved air, freezes to clear transparent ice which may give indications of structure by transmitted light or on melting, but has usually no external crystalline form. Solid, well-defined crystals of ice are extremely rare.

Though liquid water, if perfectly pure and free from dust, can be cooled to about -15° without solidification (Thomson, Trans. Roy. Soc. Edin. 1849, 18, 575; Sorby, Phil. Mag. 1859, [iv.] 18, 105), ice always melts at a definite and fixed temperature at atmospheric pressure,

and its melting-point is therefore used to define the zero point of thermometric scales. The melting-point is lowered by increase of pressure, and this has been adduced in explanation of the phenomenon of *regelation* or welding of separate pieces of ice, and is illustrated by the well-known experiment in which a weighted loop of wire cuts through, but does not sever, a block of ice.

Ice separating from under-cooled water forms hexagonal crystal skeletons or spherulites, according to the degree of under-cooling, and is obtained in feathery forms from very dilute solutions; but inoculation of under-cooled pure water with these forms produces identical forms of ice (Hartmann, Zeitsch. anorg. Chem. 1914, 88, 128).

The crystalline form of ice is hexagonal-bipyramidal with the axial ratio $a:c$ approximately 1:1.6 (Nordenskiöld, Oefv. Akad. Förh. Stockholm, 1860, 17, 439; Rinne, Ber. Sachs. Ges. Wiss. 917, 69, 57). Its X-ray spectrum has been investigated (St. John, Proc. Nat. Acad. Sci. 1918, 4, 193; Dennison, Phys. Rev. 1921, 17, 20), and the results are interpreted by Bragg (Proc. Physical Soc. 1922, 34, 98) on the assumption that the molecules are separated into positive and negative ions arranged in a hexagonal lattice in such a manner that each oxygen atom is situated at the centre of gravity of four neighbouring oxygen atoms, from each of which it is separated by a hydrogen ion situated midway between. The extremely open character of the structure is in accordance with the low density of ice.

The velocity of crystallisation of water in long tubes, 12 mm. external and 7 mm. internal diameter, increases with the degree of under-cooling as follows:—

Temp.	-2°	-3.61°	-4.67°	-5.86°	-6.18°	-7.10°	-8.19°	-9.07°
Velocity cm./min.	31.6	48.4	71.4	107.1	114.7	266.7	415.2	684.0

(Walton and Judd, J. Phys. Chem. 1914, 18, 722, which see for a useful summary of earlier work), but at any given temperature is retarded by the presence of dissolved acids, salts, dyes, &c. The retardation is not a colligative property of the solute, but appears to depend upon the extent to which the solute is hydrated in solution (Walton and Brann, J. Amer. Chem. Soc. 1916, 38, 317; Brann, *ibid.* 1918, 40, 1188).

Colloidal ice has been obtained by cooling

solutions of water in ether or chloroform, in some cases with the use of fatty acids or rubber as protective colloids (v. Weimarn and Ostwald, Zeitsch. Chem. Ind. Kolloide, 1910, 8, 181; J. Russ. Phys. Chem. Soc. 1910, 42, 236).

Elasticity.—A mass of ice yields steadily to pressure, e.g. a bar of glacier ice supported at the ends and loaded in the middle is slowly deflected, and ice compressed in a cylinder flows steadily, and the flow once started can be maintained by relatively small pressures (How,

Ann. Physik, 1902, [iv.] 8, 405). Curiously, the bar of ice when relieved from its load slowly recovers its original form. It has been shown that a bar of ice cut from a single crystal with its length perpendicular to the optic axis is brittle and does not yield to tension or pressure (McConnel, Proc. Roy. Soc. 1891, 49, A. 323), and the behaviour of ordinary ice is therefore

probably attributable to slipping of crystal layers of finite thickness.

The conflicting results of earlier investigators are thus explained, and it is necessary only to record the determinations of modulus of elasticity E and bending moment B in grm. cms. made by Hess (*l.c.*) upon bars of ice cut from single crystals as tabulated below:

Elasticity of Ice.

Load in gm. on beam 1.2 cm. \times 2.5 cm. \times 4-16 cm.	Length parallel to crystal axis			Width parallel to crystal axis			Thickness parallel to crystal axis		
$E \times 10^{-10} =$	2000	5000	6000	1000	2000	3000	1000	1500	2000
$B =$	0.54	0.70	0.75	3.5	2.9	4.0	1.6	2.0	2.0
	1350	3400	4000	1500	3000	4450	1600	2350	3100

The recovery of bent ice on removal of stress is much greater than similar effects in other substances, and has not been adequately explained.

The rate of plastic flow of ice is small at low temperatures, but increases rapidly near the melting-point (Tammann, Ann. Physik, 1902, [iv.] 7, 198; Slatowratsky and Tammann, Zeitsch. physikal. Chem. 1905, 53, 341), and a similar variation characterises the hardness of ice. On Mohs' scale the hardness is about 1.5, but as measured by the penetration of a steel rod into a block of ice it is considerably greater at temperatures from -37° to -12° than at about -7° , and at the melting-point ice becomes relatively quite soft (Andrews, Proc. Roy. Soc. 1886, 40, A. 544).

Frictional resistance to motion on the surface of ice is clearly related to the above phenomena; it is greater for small pressures than for large, the respective values of the coefficient of friction being 0.36 and 0.17 (Morphy, Phil. Mag. 1913, [vi.] 25, 133).

Liquid water appears to have, like some other liquids, tensile strength. If a glass tube containing only water and its vapour and nearly filled with the former be warmed until the liquid thus expanded just fills the tube, and then allowed to cool, the water continues to fill the tube even when its volume is thereby greater by about $\frac{1}{100}$ th than that corresponding to its temperature. It is hence calculated that the tensile strength of water is some 700-900 lbs./sq. in. (Berthelot, Ann. Chim. 1850, [iii.] 30, 232; see also Budgett, Proc. Roy. Soc. 1912, 86, A. 25). The rupture of a stream of water flowing through a constriction in a pipe is probably a true tensile rupture, especially as the tensile strength, deduced from the velocity at which rupture occurs, diminishes with rise

of temperature and becomes zero at about 250° (Skinner and Entwistle, Proc. Roy. Soc. 1915, 91, A. 481; Skinner and Burfitt, Proc. Physical Soc. 1919, 31, 131), in accordance with Larmor's calculation from van der Waal's equation that the tensile strength of water could subsist only up to about 265° (Larmor, Proc. London Math. Soc. 1916, [ii.] 15, 191).

The compressibility of water has already been discussed in relation to the attendant volume change, but it must here be noted that it connotes a *bulk elasticity* which is related in the usual manner to the velocity of sound in the medium. Experimental determinations of the velocity have given the following results: At 8.1° , 1435 metres/sec. (Colladen and Sturm, Ann. Chim. 1827, [ii.] 36, 113, 225; Pogg. Ann. 1828, 12, 39, 161); at 3.9° , 1399 m./sec.; at 13.7° , 1437 m./sec.; at 25.2° , 1457 m./sec. (Martini, Wied. Beibl. 1888, 12, 566; Nuovo Cimento, 1909, [v.] 18, 441).

The velocity of sound in water vapour is 401 m./sec. at 0° (Masson, Compt. rend. 1857, 44, 464; Phil. Mag. 1857, [iv.] 13, 533), and about 410 m./sec. at 100° (Jäger, Wied. Ann. 1889, 36, 165).

Viscosity.—The viscosity of water vapour has been determined at about the ordinary temperature by several observers with substantially concordant results as follows:—

At 0° , $\eta = 90.4 \times 10^{-6}$ C.G.S. units; at 16.7° , $\eta = 96.7 \times 10^{-6}$ (Puluj, Sitzungsber. Akad. Wiss. Wien. 1878, 78 (2), 279); at 18.8° , $\eta = 97.5 \times 10^{-6}$ (Kundt and Warburg, Pogg. Ann. 1875, 155, 337, 525); at 28.9° , $\eta = 100.6 \times 10^{-6}$ (H. Vogel, Ann. der Physik, 1914, 43, 1235).

For undercooled water below 0° the most probable values of the viscosity are those given in Table 22; for water from 0° – 100° substantially

TABLE 22.

White and Twining, Amer. Chem. J. 1913, 50, 380.

concordant determinations are recorded by a number of observers, and the more important are given in Table 23. The viscosity progressively diminishes with rise of temperature both as these data show and above 100° (becoming 0.00223 at 124° and 0.00181 at 158°: Hosking; Bingham and White; Table 23), but the variation does not follow any simple law and can only be expressed by empirical formulae which it is unnecessary to record.

Water under high pressures of the order of 400 atm. is less viscous than uncompressed water

at temperatures up to about 35°; at higher temperatures the viscosity of water is increased by increase of pressure, just as is that of most other liquids at all temperatures (Hauser, *Drude's Ann.* 1901, 5, 597).

The viscosity of ice, regarded as a fluid, has been estimated from the movement of glaciers to be of the order of $200-300 \times 10^{12}$ (Deeley and Parr, *Phil. Mag.* 1913, [vi.] 26, 85; 1914, [vi.] 27, 153), but measurements on blocks of ice or single crystals give widely divergent results (see e.g. McConnell, *Proc. Roy. Soc.* 1890, 48, A

259). Hess found that the apparent value of the viscosity depends upon the direction of flow in relation to the original crystal axis, and varies also with time in the manner indicated by the results given in Table 24. It would appear that even a single crystal of ice may yield by slipping on cleavage surfaces, with consequent recrystallisation similar to that which is familiar in the case of metals yielding to stress.

Surface tension.—Water has a higher surface tension than any other common liquid except mercury. No data are available for its value in undercooled water; Table 25 gives the values of σ , the specific cohesion, and of γ , the surface tension in dynes/cm., at 1° intervals of temperature from 0°–90°; the progressive

diminution of γ with rise of temperature may be expressed by $\gamma = 76.09 (1 - 0.002028t)$ (Senti, *Journ. de Physique*, 1897, [iii.] 6, 183), or better, by $\gamma = \gamma_0 (1 - 0.00190179t - 0.000002499t^2)$ (Forch, *Ann. Physik*, 1905, 17, 744; see also Reinhold, *Ber.* 1913, 15, 903). Whilst the relative values of the surface tension at different temperatures are well represented by Table 25, the absolute values may be in error; in very careful measurements of the capillary rise (Richards and Coombs, *J. Amer. Chem. Soc.* 1915, 37, 1656; Richards and Carver, *ibid.* 1921, 43, 827) and of the 'drop-weight' of water (Harkins and Brown, *J. Amer. Chem. Soc.* 1919, 41, 499) a number of sources of error incidental to both methods have been discovered and eliminated, and the final results

TABLE 23A.

VISCOSITY OF WATER, γ IN C.G.S. UNITS IN THE NEIGHBOURHOOD OF ITS POINT OF MAXIMUM DENSITY.

Thorpe and Rodger (*loc. cit.*) have determined by the tube method the Viscosity of Water at various Temperatures in the vicinity of its point of maximum density, with the results seen in the annexed table.

Mean temp.	γ		Difference.

8.01	-01377	-01375	-00002

[Note on Table 23a: The viscosity of water at different temperatures has also been determined by the rotating cylinder method by Leroux (Ann. Physique, 1925, [x.] 4, 163), the water being contained between two concentric cylinders, of which the outer is rotated at known velocity and the resulting twisting moment on the inner cylinder measured.

Moritz (Pogg. Ann. 70, 1847), from observations made by the method of Coulomb (oscillating disc), inferred that water had a maximum viscosity in the neighbourhood of 4° . Other observers, and more especially Poiseuille and Sprung, using the tube method, were unable to detect any peculiarity in the rate of change of viscosity at temperatures at about the point of maximum density. The observations of Thorpe and Rodger lend no support to the conclusions of Moritz. It must be borne in mind, however, that the anomalous change in the density of water amounts only to about 1 part in 10,000; hence, since the accuracy attained in these special observations of viscosity probably does not exceed 1 in 5,000, it may be doubted whether any anomalous change in viscosity of the same order of magnitude as that observed in the case of the density would be detected by any of our present experimental methods.]

H. Hess, Ann. Physik. 1902, [iv.] 8, 405.

show respectively $\gamma_{100} = 72.75$ and $\gamma_{100} = 72.800$ respectively. Richards and Carver (*loc. cit.*) have proved experimentally, by a very ingenious optical method, that the surface of water is actually tangential to a properly wetted glass surface, and thus that the ordinary formula connecting surface tension and capillary rise holds precisely. Minute traces of dust or impurities have a considerable effect on the

surface tension, and precise measurements can only be made in a totally enclosed apparatus; Harkins and Brown have found that the capillary rise is affected by 'steaming' the tubes beforehand with the vapour of the liquid under investigation.

Absorbed or dissolved gases affect the surface tension; Richards and Carver find $\gamma_{100} = 72.73$ in air as compared with 72.75 in *vacuo*; dis-

Volkman, Wied. Ann. 1890, 11, 177; 1882, 17, 353; 1895, 56, 457 (0° - 40°).
 Brunner, Pogg. Ann. 1847, 70, 481 (40° - 80°).

solvent CO_2 , CO , N_2O , H_2S , H_2O , and N_2 similarly cause a small lowering of the surface tension (Quinke, Pogg. Ann. 1870, 139, 1, 89; 1877, 160, 337; Volkman, Wied. Ann. 1880, 11, 177; 1882, 17, 353; 1894, 53, 653; 1895, 56, 457; 1896, 66, 220; Forch, Wied. Ann. 1899, 68, 301; Ann. Physik, 1905, [iv.] 17, 750; Bhatnagar, J. physical. Chem. 1920, 24, 716).

By measurement of the amplitude of the wave produced when a stream of water emerges under pressure from capillary of elliptical cross-section, evidence has been obtained that the surface tension in a freshly formed surface of

water is about 0.5 dyne/cm. less than in old surfaces (Meyer and Stocker, Zeitsch. Elektrochem. 1916, 22, 5; Stocker, Zeitsch. physikal. Chem. 1920, 94, 149).

From the cooling effect of adiabatic expansion of water, the internal pressure has been calculated to be 2150 atmospheres (Parsons and Cook, Proc. Roy. Soc. 1911, A. 85, 332).

The surface tension in the interface between water and several organic liquids is given in Table 26; it is always less, and usually much less, than in pure water.

The coefficient of diffusion of water vapour

at 760 mm. pressure into air (I), carbon dioxide (II), and hydrogen (III) in cm.²/sec. is given in Table 27.

Molecular data have been calculated as follows for water vapour at 0°:

Mean molecular velocity, 58,650 cm./sec.

Mean free path, at 760 mm. pressure, 4.04×10^{-8} cm.

Molecular diameter, about 4.0×10^{-8} .

The number of molecules per gram-molecule of liquid water is estimated to be 8.5×10^{23} (Sand, Trans. Faraday Soc. 1919, 15, 84).

THERMAL PROPERTIES.

Conductivity.—The principal data for the thermal conductivity of liquid water are given in Table 28; the considerable variation among them is a measure of the difficulty of making a precise measurement of the conductivity, owing to the effects of convection and radiation, but it is clear that it is very small as compared with that of metals, yet greater than that of other non-metallic liquids (e.g. alcohol 0.00055; benzene 0.00033). The conductivity shows a linear increase with temperature and may be represented by conductivity = $0.001325(1 + 0.002984t)$ Cal./cm. sec. degree (Jakob, *l.c.*).

The thermal conductivity of solid ice is about four times that of water, the most probable of the recorded values being 0.0057 (Neumann,

Ann. Chim. 1862, [iii.] 66, 183; Phil. Mag. 1863, [iv.] 25, 63), 0.0052 (Straneo, Atti R. Accad. Lincei, 1897, [v.] 6, (2), 262), and 0.0052 at 0°; 0.0058 at -57°, 0.0052 at -117° (Lees, Phil. Trans. 1898, 191, A, 399; Proc. Roy. Soc. 1905, 74, 337); in all cases gm. calories transmitted per sec. per sq. cm. through a thickness of 1 cm. for 1° temperature drop.

As a matter of common experience the thermal conductivity of snow is much less than that of ice, but it varies considerably with the nature and density of the snow, and attempts to measure it have given widely diverse results. Approximately it is of the order of $\frac{1}{10}$ th to $\frac{1}{15}$ th that of ice (Andrews, Proc. Roy. Soc. 1881, 40, 544; Abela, Rep. Meteorol. Acad. Petrograd, 1892, 16, 53; Hjelström, Oef. Akad. Stockholm, 1889, 46, 669; Jansson, *ibid.* 1901, 58, 297; Okada, J. Meteorol. Soc. Japan, 1905, 241).

Change of State.—The general relation of the state of aggregation to temperature has been discussed, but reference should be made to the undercooling of the liquid and vapour and the superheating of the liquid.

In the absence of nuclei, water vapour may be cooled much below its saturation temperature without deposition of visible water. Solid nuclei, such as particles of dust, spores, &c., may, and in ordinary air do, cause the condensation of liquid water immediately the saturation temperature is reached. Even less tangible nuclei will suffice. O. T. R. Wilson's simple and ingenious method of rendering the track of α -particles in a gas susceptible to visual observation or photographic record depends upon the fact that gaseous ions (produced by collision between the α -particle and molecules) will act as nuclei for the condensation of super-saturated water vapour.

Similarly, pure water in *vacuo*, in fine capillary tubes, or covered with petroleum, may be cooled some 15° below zero without solidification; even when slightly undercooled, water may be caused to crystallize by mechanical shock or agitation in the absence of nuclei (S. W. Young, J. Amer. Chem. Soc. 1911, 33, 148; Young and Cross, *ibid.* 1911, 33, 1375; Young and van Sicken, *ibid.* 1913, 35, 1067; Hartley and Thomas, J. Chem. Soc. 1906, 89, 1013). There is thus for water no evidence of the so-called 'metastable,' as distinct from 'labile,' condition in which nuclei are essential to crystallisation.

Liquid water is readily superheated; it is indeed difficult to boil water without slight local superheating, and very frequently the superheating is so considerable that when steam bubbles originate they increase in size with explosive violence, producing 'bumping.' In fresh distilled water minute bubbles of dissolved

air expelled on heating serve as nuclei for steam bubbles and minimise the bumping, and the same effect is frequently attained artificially by introducing air-filled porous solids, e.g. broken pottery, or a fine stream of air into the liquid. Without special precautions air-free water can be heated to 130° (see e.g. Donny, Ann. Chim. 1844, [iii.] 16, 167; Gernez, *ibid.* 1875, [v.] 4, 335; Krebs, Pogg. Ann. 1868, 133, 673; 1869, 136, 144; 1869, 138, 489), and if it is suspended in a mixture of olive oil and linseed oil of its own density it may be heated to 178° without boiling (Dufour, Ann. Chim. 1863, [iii.] 68, 370).

Latent Heat.—Heat is absorbed and rendered 'latent' both in the fusion of ice and in the evaporation of ice or water.

Table 29 gives the values of the heat of evaporation of water (frequently and more conveniently called the latent heat of steam) determined by a number of independent investigators at various temperatures from 0°–180°. The value at 100° is an important constant, and for this the most probable round value is 539.0 15° gm. cal. per gram.

Table 30 similarly gives data for the latent heat of fusion of ice, which usefully can be, but commonly is not, called the latent heat of water. Bunsen's value is undoubtedly erroneous, but if corrected for the difference in density between old and new ice (g.s.) becomes 79.67 in good agreement with more recent determinations. The rounded value 79.7 may be used with confidence for most purposes.

There is, of course, a direct relation between the latent heat of steam or water and the effect of dissolved substances upon the boiling-point and freezing-point.

The molecular elevation of the boiling-point is 0.52° (Beckmann, Zetsch. physikal. Chem. 1891, 8, 223; 1906, 63, 177), and the molecular

WATER.

355

depression of the freezing-point is 1.66° (Racoult, *physikal. Chem.* 1906, 63, 441; Zetsch, *Electrochem.* 1920, 26, 238; Dickinson and Osborne, *Proc. Roy. Soc.* 1910, A, 83, 459; Roth, *Zeitsch. physikal. Chem.* 1906, 63, 441; Zettsch, *Electrochem.* 1920, 26, 238; Dickinson and Osborne, *J. Franklin Inst.* 1915, 179, 499).

Specific Heat.—The specific heat of steam at the temperature and pressure of saturation and at higher temperatures or lower pressures (when it is unsaturated or 'superheated') is of great theoretical and practical importance in connection with the generation of steam and its use in all types of prime movers. Table 31 gives the values at temperatures from 80°-550° and under pressures from 0.5 to 30 atmospheres. The specific heat of saturated steam increases

with temperature and pressure; that of unsaturated steam at constant pressures less than about 9 atmospheres decreases to a minimum value and then increases progressively with temperature; the minimum of specific heat occurs at temperatures which increase with pressure, and may occur at pressures above 9 atmospheres at higher temperatures than have yet been subject to experiment.

The specific heat of steam at or near

Knoblauch and Balach, *Zeitsch. Ver. Ing.* 1922, 66, 418; based on previous work by Knoblauch et al.

atmospheric pressure has been measured at still higher temperatures; up to 1400° it is represented by $C_{p,0.1} = 0.4669 - 0.0168t + 0.044t^2$ or $C_{p,0.1} = 0.4544 + 0.006925 \times 10^{-6}t^3$ (Holborn and Henning, *Ann. Physik*, 1907, [iv.] 23, 808; see also *Ann. Physik*, 1905, [iv.] 78, 739; *Wiss. Abh. Phys.-Tech. Reichsanstalt*, 1905, 4, 131; and Lorenz, *Phys. Zeit.* 1904, 5, 383). The ratio of the specific heats at constant pressure and constant volume is about 1.3 at 103°,

1.330 at 110°, 1.313 at 120°, and 1.312 at 130° (Tretz, Bonn, 1903).

The heat capacity of water, usually at 15°, is used as a standard, and its variation with temperature is therefore of great practical importance and has been the subject of many precise investigations. Some of the more important results are given in Table 22 (see also, *inter alia*, Lédin, *Mitt. naturw. Ges. Winterthur*, 1906; *Dissertation, Ann. der Physik*,

1906, [iv.] 16, 393; Barnes, Phil. Trans. 1902, A. 199, 149; Barnes and Cooke, Phys. Review, 1902, 15, 65; Cotty, Ann. Chim. 1911, [viii.] 24, 333.

With rise of temperature from 0°C. the specific heat decreases rapidly to a minimum value and then increases more slowly at a rate which itself increases but slightly with temperature; the measurements of Callendar and of Jaeger and Steinwehr agree in placing the minimum of specific heat at about 35°.

Numerous formulae have been proposed to express the variation of the specific heat of water with temperature, but they have no physical basis; as an example, the formula $C_p = 1.00733 - 0.0007416t + 0.000016845t^2$

$$- 0.000,000,09552t^3$$

where $C_{100} = 1$, agrees well from 0°–100° with the best experimental values (Narbutt, Zeitsch. Physik. Chem. 1918, 19, 513).

Below 0° the specific heat of undercooled

water increases very rapidly with fall of temperature, attaining the value 1.0155 at –5° (Barnes, l.c.).

The specific heat of water at 0° is decreased by 0.0061025 if the pressure is increased by one atmosphere.

The specific heat of ice is less well known; it is about half that of water at 0° and becomes quite small at low temperatures. A number of determinations are given in Table 33. It appears to increase very rapidly just below the melting-point (A. W. Smith, Phys. Review, 1903, 17, 193), probably owing to physical inhomogeneity.

Entropy.—The entropy of ice at 0°, calculated from absolute zero, is found to be 9.96 per gram molecule; adding 5.26 the entropy of fusion of ice at 0°, and 1.58 that due to heating water from 0° to 25°, the entropy of water at 25° is 16.8 per gram molecule (Lewis and Gibson, J. Amer. Chem. Soc. 1917, 39, 2575).

OPTICAL PROPERTIES.

Crystalline luminescence.—It has been reported that if water be rapidly frozen, bright flashes of luminescence are observed (Trautz, Zeitsch. physikal. Chem. 1905, 53, 9).

Colour: absorption of light.—There is much evidence, irrelevant here, that the bright blue colour often observed in water, notably in that of china-clay settling pits, reservoirs for large scale water-softening, and some lakes, *e.g.* Lake Geneva, is due to the scattering of light by

Hottel, Ann. Physik. 1916, 55, 495.

minute suspended particles. But glacier ice and the water produced therefrom, which are undoubtedly very pure, show by transmitted light a distinct greenish-blue colour (H. Davy, *Collected Works*, 1840, 9, 199; Bunsen, *Pogg. Ann.* 1851, 83, 197; Rayleigh, *Nature*, 1910, 83, 49).

Pure distilled water in a tube several metres long and blackened internally is quite definitely greenish-blue by transmitted light.

As ozone is deep blue, liquid oxygen pale slightly greenish-blue, and hydrogen peroxide, methyl alcohol, ethyl alcohol and similar simple hydroxyl compounds are bluish-green, this colour is probably an intrinsic property of pure water. In smaller thicknesses water appears colourless.

The absorption spectrum of water in the visible region accords with its observed colour. In the red from $660\text{--}040\mu$ the absorption coefficient is about 0.3, in the orange at approximately 600μ it is about 0.15, whence it falls rapidly to about 580μ , and is less than 0.05 throughout the regions of the spectrum from yellow to violet (von Aufsess, *Die Farbe der Seen*, München, 1903). The absorption in the ultra-violet has been studied by Kreusler (*Ann. der Physik*, 1901, [iv.] 6, 412).

Water is opaque to infra-red radiation over a wide range of wave-length. The most recent measurements are given in Table 34 (see also Bode, *Ann. Physik*, 1909, [iv.] 30, 326; von Bahr, *Ber.* 1913, 15, 731; and, for the fine structure, Sleator, *Astrophys. J.* 1918, 48, 125; Wichmann, *Physikal. Zeitsch.* 1921, 22, 535; *Ann. Physik* 1922, [iv.] 66, 501).

Water vapour is more transparent than liquid water to infra-red radiation. The opacity of the atmosphere to such radiation is mainly due to its content of water vapour, and does not extend to wave-lengths shorter than about 11μ ; the absorption by an equivalent layer, say 2 cm., of liquid water is complete down to 1.2μ . The difference gave rise to prolonged controversy between Magnus and Tyndall before its nature was established (Magnus, *Pogg. Ann.* 1861, 112, 497; 114, 635; 1863, 118, 576; 1864, 121, 186; 1866, 127, 613; 1867, 130, 207; Tyndall, *Proc. Roy. Soc.* 1860, 10, 37; 1861, 11, 558; 1879, 30, 10; 1881, 31, 307, 478; 1883, 35, 21; *Phil. Mag.* 1861, [iv.] 22, 377; 1862, [iv.] 23, 252; 1863, [iv.] 26, 44; 1866, [iv.] 32, 118; 1867, [iv.] 33, 425).

Water also absorbs X-rays (for details, see Hewlett, *Phys. Review*, 1921, 17, 284; Richtmyer, *ibid.* 1921, 18, 13).

Refractive Index.—Table 35 gives the refractive index of water for light of various wave-lengths and at temperatures from $0^{\circ}\text{--}80^{\circ}$; these values are substantially confirmed by more recent and very precise determinations, which give, for the iron line E ($\lambda=6270.11$)

$$n_D^{15^{\circ}} = 1.3356359$$

and, for sodium light, the following values referred to air and in *vacuo*:

Temperature .	20°	25°	30°
n_D in air .	1.33299	1.33248	1.33190
n_D in <i>vacuo</i> .	1.33335	1.33284	1.33225

Flatow, *Ann. Physik*, 1908, [iv.] 12, 85: the values given by Flatow are in substantial agreement with the determinations of other observers cited, e.g. Landolt-Börnstein, *Tabellen*, 1923, p. 946.

(Gifford, Proc. Roy. Soc. 1906, A, 78, 406; Baxter, Burgess and Daudt, J. Amer. Chem. Soc. 1911, 33, 893).

* The dispersion equivalent $n_D - n_A$ and the dispersive power $(n_D - n_A)/(n_D - 1)$ are given as follows:

Temperature	0°	10°	20°	30°	40°	50°	60°	70°
Dispersion equivalent	0.0147	146	148	145	148	147	144	141
Dispersive power	0.0429	439	445	438	449	448	441	435

(Gladstone and Dale, Phil. Trans. 1858, 148, 887; 1863, 153, 323).

Measurements with electrical waves, $\lambda = 3.5$ – 4.5 cm., show that the refractive index of water increases with the wave-length and that water exhibits anomalous dispersion (Marxkyng, Bull. Acad. Sci. Cracow, 1911, 123).

Ice exhibits double refraction and is optically positive. The refractive indices for sodium light are for the ordinary ray 1.3091 and for the extraordinary ray 1.3104 (Pulfrich, Wied. Ann. 1888, 34, 336; cf. the values 1.3083 and 1.3133 respectively of Meyer, *ibid.* 1887, 31, 322).

Scattering of Light.—It has been shown that pure water, free from ultra-microscopic suspended particles, scatters light, and that the scattered light is polarised, but the interpretation of the phenomenon is as yet incomplete or lacking (see Einstein, Ann. Physik. 1910, 33, 1275; Cabannes, J. Phys. Chem. 1920, [vi.] 1, 129; Martin, J. Phys. Chem. 1920, 24, 248; 1922, 26, 75; 1923, 27, 558; Rayleigh, Proc. Roy. Soc. 1920, 97 A, 435; Raman, *ibid.* 1922, 102, A, 151; Phil. Mag. 1923, 45, 625).

MAGNETIC AND ELECTRICAL PROPERTIES.

Coefficient of magnetisation.—The coefficient of magnetisation for water referred to unit mass has been determined by several observers to be about -0.72×10^{-6} C.G.S. units at 20° (de Haas

T°	10°	20°	30°	40°	50°	60°	70°	80°	90°
Ω	0.0098	1.0001	1.0008	1.0018	1.0029	1.0041	1.0053	1.0065	1.0074

Electrical conductivity.—Pure water is a very poor conductor of electricity. The purest water ever obtained (see Purification) had a specific conductivity 0.043×10^{-8} reciprocal ohm (mho) at 18°.

It is calculated that the conductivity of

and Drapier, Ann. Physik, 1913, [iv.] 42, 673; Weiss and Piccard, Compt. rend. 1912, 155, 1234; Piccard, Arch. Sci. phys. nat. 1913, [iv.] 35, 458; see also Gray and Birse, J. Chem. Soc. 1914, 105, 2707; Hayes, Phys. Rev. 1914 (2), 3, 295). This coefficient has a temperature coefficient of about $+0.00012$ at 20°.

Ice is said to be diamagnetic (Brunner, Pogg. Ann. 1850, 79, 173).

Magneto-optic Rotation.—The rotation of the plane of polarisation of light by a given thickness of water in a given magnetic field depends upon the wave-length of light and upon the temperature. The specific rotation (for 1 cm. of liquid in unit magnetic field) for the D line at 18° is $\omega_{18}^D = 0.01309$ minutes of arc (Agerer, Sitzungsber. Akad. Wiss. Wien. 1905, 114, 830), and its variation with temperature is given between 3° and 98° by $\omega^D = 0.01311(1 - 0.0,305t + 0.0,305t^2)$ (Rodger and Watson, Zeitsch. physikal. Chem. 1896, 19, 357).

The molecular magnetic rotation of water at 4°C. is taken as the standard, unity, for fixing that of other liquids, their molecular magnetic rotation being then given by

$$\Omega = \frac{\omega \times \text{mol. weight}}{18}$$

Thus the variation of the molecular magnetic rotation of water is of practical importance and is illustrated by the following data (Rodger and Watson):—

TABLE 36.
DIELECTRIC CONSTANT OF WATER, ϵ .

3. Turner, Zeitsch. physikal. Chem. 1900, 35, 335.
4. Rukop, Diss. Grieswald, 1911.
5. Drude, Wied. Ann. 1896, 59, 17.

it varies very rapidly with temperature (see Noyes, Kato and Rosman, *J. Amer. Chem. Soc.* 1900, 32, 154).

Ice is quite a good insulator; its specific resistance is 4865 megohms at 0° and 33,540 megohms at -17° . Thus, a cable, the insulation of which is defective through moisture, will frequently show a good insulation test when exposed to severe frost.

Dielectric capacity.—The dielectric constant for steam at 145° and 760 mm. is $\epsilon=1.00705$, and its variation with temperature is expressed by $\epsilon_t = \epsilon_{t_1} - \alpha(t_t - t_1)$ where $\alpha = 1.4 \times 10^{-4}$ and $t_1 = 145^\circ$ (Bädeker, *Zeitsch. physikal. Chem.* 1901, 36, 305).

Table 36 gives a series of values of ϵ for water for different wave-lengths. The dielectric constant varies with pressure from 7–200 atmospheres by about 0.0046 p.c. per atmosphere (Falckenberg, *Ann. Physik.* 1920, [vi.] 61, 145).

The dielectric constant for ice for $\lambda=5000$ cm. at -18° is 3.1 (Abegg, *Wied. Ann.* 1898, 65, 229) and for $\lambda=75$ cm. at -190° is 1.76–1.88 (Behn and Kiebitz, *Boltzmann's Festschrift*, Leipzig, 1904, 610).

The ionising potential for water vapour is calculated to be 8.64 volts (Compton, *Phys. Review*, 1916, (2), 8, 412).

THE CHEMICAL PROPERTIES OF WATER.

Molecular constitution.—It was formerly supposed that the relatively high density of water vapour in the neighbourhood of the boiling-point and at lower temperatures connoted the presence in it of molecules more complex than H_2O (see e.g. Bose, *Zeitsch. Elektrochem.* 1908, 14, 269; Oddo, *Gazz. chim. ital.* 1915, 45, i. 319; 395), but if the experimental values are corrected for the deviation of water vapour from the ideal gas-laws and recalculated by the Clausius-Clapeyron equation the results afford no evidence whatever for any deviation from the simple formula H_2O , and this must, therefore, be assumed to represent correctly the molecular state of water vapour (Kendall, *J. Amer. Chem. Soc.* 1920, 42, 2477; Menzies, *ibid.* 1921, 43, 851).

On the other hand, experiments with a modified Wilson's expansion apparatus, interpreted in accordance with Lenard's theory, indicate the presence of about 1.9×10^{-11} p.c. of uncharged nuclei of relatively large dimensions which are most probably polymerised molecules of the type $(H_2O)_n$ or $(H_2O)_m$ (Andr n, *Ann. Physik.* 1917, [iv.] 52, 1).

With regard to liquid water, there is a great body of evidence pointing to the presence of complex molecules. It is now fairly generally held that the abnormality of water as compared with other liquids in so many physical properties is due to polymerisation. This explanation was first advanced by Whiting (*A New Theory of Cohesion Applied to the Thermodynamics of Liquids and Solids*, Harvard University, Cambridge, Mass. 1884, p. 70), who pointed out that water at 0° may contain 25–33 p.c., and at 100° 17–28 p.c. of dissolved ice, and that the observed expansion of 4 p.c. by volume in this interval is the resultant of a normal expansion of some 8–10 p.c. by volume and a contraction due to the melting of the

dissolved ice. Eight years later, R ntgen (*Wied. Ann.* 1892, [5] 45, 91) independently suggested that water consists of 'ice molecules' and 'water molecules,' the former being more complex but less dense than the latter.

Later, Sutherland elaborated the hypothesis still further and, possibly influenced by Traube's theory that normal liquids consist of 'liquidogenic' and 'gasogenic' molecules, supposed water to consist of single, double and triple molecules, to which he gave the names *hydrol* (H_2O), *dihydrol* (H_4O_2), and *trihydrol* (H_6O_3).

In liquid water we then have the equilibria: $2H_2O \rightleftharpoons 3H_4O \rightleftharpoons 6H_6O$. Steam is hydrol; ice is supposed to consist chiefly or wholly of trihydrol. Because of the lower density of ice it seems probable that trihydrol is less dense than dihydrol; and our present knowledge of the crystal structure of ice (*q.v.*) accords well with the view. Whiting's theory, originally propounded simply to explain the anomalous expansion of water, has been applied successively to the other physical properties of water, and has been found to accord so well with the observed facts that its substantial truth seems clear (see e.g. Walden, Guye, Bonsfield and Lowry, Sutherland and Nernst, *Trans. Faraday Soc.* 1910, 6, 71–123). It is of interest to consider some examples.

The melting of ice is attended by considerable absorption of heat and decrease of volume; *ex hypothesi* then, these phenomena characterise the conversion of trihydrol to dihydrol. Therefore, in accordance with Le Chatelier's theorem, either rise of temperature or increase of pressure will tend to dissociate trihydrol and so reduce the proportion present in water. If the volume change of water on heating is the resultant of (a) contraction due to depolymerisation of trihydrol and (b) the normal expansion of dihydrol, the preponderance of (a) up to 4° (owing to the relatively higher proportion of trihydrol then present) can explain the observed net contraction between 0° and 4° . Similarly, the diminution of the proportion of trihydrol by pressure explains the lowering of the temperature of maximum density by increase of pressure.

The minimum of compressibility of water about 50° is best accounted for by Bonsfield and Lowry's extension of the hypothesis (*Trans. Faraday Soc.* 1910, 6, 85); they assume that monohydrol, like trihydrol, is less dense than dihydrol, and constitutes an important proportion of water above 50° . The increased proportion of a less dense and therefore more compressible constituent both above and below that temperature then accords with the observed greater compressibility (see also Richards and Palitzsch, *J. Amer. Chem. Soc.* 1919, 41, 63, for a discussion of this matter, and Pagliani, *Gazz. chim. ital.* 1920, 50, i. 136).

Similarly convincing explanations have been elaborated for the observed variations with temperature and pressure of the viscosity (Pagliani, *l.c.*), specific heat (Nernst, *J. Chem. Soc.* 1910, A. ii. 844), index of refraction (Ch naveau, *Compt. rend.* 1913, 156, 1972), magnetisation (Piccard, *ibid.* 1912, 155, 1497), dielectric constant (Falckenberg, *Ann. Physik.* 1920, [iv.] 61, 145), &c.

Measurements of the molecular weight of water by the cryoscopic and ebullioscopic

methods in supposedly neutral solvents give no evidence of association, but in fact water does react (*sic* *infra*) with such solvents in a manner which renders the method untrustworthy. More reliable conclusions may be drawn from measurements upon dilute solutions in such definitely reactive solvents as phosphorus oxychloride or nitrogen tetroxide, and these give concordant values for the molecular weight approximating closely to 36, indicating the formula H_2O_n (Oddo, *Gazz. chim. ital.* 1916, 46, i. 172; see also Bruni and Amadori, *Gazz. chim. ital.* 1910, 40, ii. 1). Attempts to calculate the complexity of ice molecules in solution from the variation of expansibility, compressibility and specific heat on the assumption that ice (H_2O_n) in solution in water retains its normal density lead to values for n around 12 (Duclaux, *Compt. rend.* 1911, 152, 1387), but this assumption is probably incorrect.

Many attempts have been made by extrapolation to calculate the properties of pure monohydrol and dihydrol, but in the present state of knowledge these are premature (see e.g. Sutherland, *J. Chem. Soc.* 1910, A. ii. 943; Oddo, *Gazz. chim. ital.* 1916, 46, i. 188).

Observations upon the formation and liquefaction of ice crystals (Skworzoff, *J. Chem. Soc.* 1911, A. ii. 970) and the phenomena of scattering of light by water suggest the presence in water of molecules of definite structure, which is intelligible on the assumption that water is actually not a simple liquid, but, at low temperatures, a solution of ice molecules in water (dihydrol). From this standpoint, the freezing-point of water is simply to be regarded as the temperature at which the concentration of trihydrol, increasing with fall of temperature, becomes equal to the solubility of trihydrol in water which, it is assumed, decreases with fall of temperature. Regulation of ice under slight pressure may conceivably occur through local

liquefaction of the ice and its resolidification on release of pressure. But neither pressure nor capillary action (alleged by Thomson, *Proc. Roy. Soc.* 1857, 3, 455; 1859, 2, 198; 1862, 11, 473; *Phil. Mag.* 1862, [iv.] 23, 497; 24, 395) are necessary, because regelation can occur under water without pressure (Faraday, *Proc. Roy. Soc.* 1860, 10, 440). On the ice solution hypothesis it is easy to understand how two blocks of ice under water may grow together by a process of solution and recrystallisation.

In addition to the evidence indicated very briefly above there is a mass of experimental work on solution which can best be explained on the foregoing hypothesis.

It is, perhaps, important to observe that if this hypothesis of the constitution of water be correct, the melting of ice, the expansion of water (at least at low temperatures), the generation of steam, &c., commonly regarded as types of simple physical change, are in fact changes of precisely the same kind as, say, the dissociation of nitrogen tetroxide or phosphorus pentachloride or the polymerisation of aldehydes, cyanogen chloride, &c., the essentially chemical character of which is never questioned. It is unnecessary to elaborate the obvious conclusion as to the validity of the distinction so frequently drawn between chemical and physical change.

CHEMICAL REACTIONS.

Dissociation and synthesis.—Water is a fairly stable compound, and is dissociated only to a small extent at about 3000°, the temperature of the oxyhydrogen flame.

In the oxyacetylene flame, which is considerably hotter, steam is largely dissociated, and the wide applicability of this flame to the welding of metals is in fact due to the consequent presence in it of free hydrogen. The following table shows the percentage dissociation of water vapour at high temperatures:—

Temperature	1124°	1207°	1290°	1432°	1510°	1590°	1695°	1984°	2370°	2488°	2561°	2656°
P.c. dissociated	0.008	0.019	0.034	0.102	0.182	0.354	0.518	1.79	4.3	6.6	9.6	11.1

The data from 1984° upwards, obtained by an explosion method, are less trustworthy than those at lower temperatures, but probably represent well enough the general trend of the reaction (Löwenstein, *Zeitsch. physikal. Chem.* 1906, 54, 715; Langmuir, *J. Amer. Chem. Soc.* 1906, 18, 1357; v. Wartenburg, *Zeitsch. physikal. Chem.* 1906, 56, 513; Bjerrum, *ibid.* 1912, 79, 513; but see Holt, *Phil. Mag.* 1907, [vi.] 13, 630).

In agreement with these facts, gaseous hydrogen and oxygen readily combine to form water when heated, when exposed to the electric spark or to a silent electric discharge, when subjected to the radiations of radioactive elements, or when exposed to ultra-violet light.

There is no evidence, though the assumption has frequently been made, that oxygen and hydrogen combine at all at ordinary temperatures in the dark, though they do so very slowly in sunlight (Baker, *Proc. Chem. Soc.* 1902, 13, 49). Isothermal increase of pressure to 56 atmospheres has no effect in promoting union (de la Roche, *Schweigger's Journ.* 1811, 1, 172; see also Degen, *Pogg. Ann.* 1836, 38, 644).

At 100° no combination can be detected in 218 days, but at 300° the formation of water is just appreciable in 65 days (Meyer and Raun, *Ber.* 1895, 28, 2904). At 400° the velocity of reaction is such that the formation of water may be recognised within a week (Bons, *J. Chem. Soc.* 1902, 81, 535; 1904, 85, 694), and thereafter the velocity of the reaction increases rapidly with temperature until at about 510°–560° explosive combination occurs. The precise value of the ignition temperature depends on the composition of the explosive mixture (being lowest, 507°, when the ratio $H_2 : O_2 = 1 : 4$) and falls with increase of pressure (Dixon and Coward, *J. Chem. Soc.* 1909, 95, 514; Dixon, *ibid.* 1910, 97, 661), but depends also upon the method of experiment and the material of the containing vessels. A small proportion of water vapour is essential to combination by normal combustion (Baker) or through the catalytic action of platinum (French, *Chem. News*, 1900, 81, 292); oxygen and hydrogen dried with phosphorus pentoxide do not react on platinum black, and only combine slowly in contact with a platinum wire at about 800°; but the explosion flame, once started, is similar in both cases and

gained gases (Dixon and Bradshaw, Proc. Roy. Soc. 1907, A, 79, 224).

Ignition of detonating gas by an electric spark is frequently a purely thermal effect, but this cannot be true of the slow combination brought about by the silent discharge (Berthelot, Ann. Chim. 1879, [v.] 17, 142; Deherain and Maquenne, Compt. rend. 1881, 93, 895, 963, 1021; Mixer, Amer. Journ. Sci. 1898, [iv.] 4, 51; Kirby, Phil. Mag. 1904, [vi.] 7, 223). A general examination of the effects indicates that the cathode column is the region of greatest chemical activity (Kirby, Phil. Mag. 1907, [vi.] 13, 289), and it seems probable that reaction proceeds by the ionisation of both gases, though short wave-length radiations akin to ultra-violet light may contribute to the effect.

Kernbaum has found (Compt. rend. 1910, 151, 319) that H_2O_2 and H_2 are produced by the silent discharge in oxygen and hydrogen mixtures, and concludes that the action of the discharge is analogous to that of ultra-violet light.

Ultra-violet light causes combination of hydrogen and oxygen and decomposes water, the reaction in either case tending to the same point of equilibrium which, for example, at 150° is that corresponding to thermal equilibrium at 1250° (Coehn, Ber. 1910, 43, 880; Coehn and Grote, Nernst's Festschrift, 1912, 136; Andréeff, J. Russ. Phys. Chem. Soc. 1911, 43, 1342). Water in a quartz vessel is decomposed thus even by sunlight (Kernbaum, Compt. rend. 1909, 149, 273; Bull. Acad. Sci. Cracow, 1911, A, 583).

The action of ultra-violet light in decomposing water is chiefly due to the radiation of very short wave-length ($\lambda=1900$), and is best observed, therefore, by the use of low-tension or new high-tension quartz mercury vapour lamps, which emit radiation relatively rich in rays of short wave-length (Tian, J. Chem. Soc. 1915, A, ii, 828; Obolewsky, Ann. Physik, 1912, [iv.] 39, 961).

In this decomposition pure hydrogen is at first the only gaseous product; later oxygen also is produced and accumulates until the composition of the mixture is that of detonating gas. This is best explained on the assumption that the primary action is an auto-oxidation producing hydrogen and hydrogen peroxide, $2H_2O \rightarrow H_2 + H_2O_2$, oxygen being formed by a secondary decomposition of the latter,

which can result from the action of moderately short wave-length radiation (λ 2500-3000) (Tian, Compt. rend. 1911, 152, 1012). In support of this theory, there is evidence that hydrogen peroxide formed from water-vapour in air by the action of ultra-violet rays in sunlight forms active nuclei for the condensation of moisture (Bleber, Ann. Physik, 1912, [iv.] 39, 1313). Contrary to suggestions which have been made, it would seem that the amount of hydrogen peroxide produced by ultra-violet light is much too small to account for the bactericidal action of the latter (see Courmont, Nogier and Roehaiz, Compt. rend. 1910, 150, 1453).

The fact that changes of potential occur at polished inert electrodes immersed in solutions of photo-sensitive coloring matters and exposed

to light may be explained on the assumption of a photochemical decomposition of the water by visible light; but there is no other evidence in support of this hypothesis (Baur and Rebmans, Helv. Chim. Acta. 1921, 4, 256).

The synthesis and decomposition of water by α -radiation is well established (Davis and Edwards, J. Soc. Chem. Ind. 1905, 24, 266; Pickel, Zeitsch. anorg. Chem. 1904, 38, 307; Lind, J. Amer. Chem. Soc. 1919, 41, 531, 551; Duane and Scheurer, Compt. rend. 1913, 156, 466). In a given spherical or cylindrical vessel the velocity of reaction depends only on the quantity of emanation present and the gas pressure, but the velocity diminishes with increase in the volume of the vessel and depends upon the hydrogen:oxygen ratio. There is reason to suppose that combination is preceded by collision-ionisation of both gases, but the mechanism of reaction is not well understood.

Catalytic action in the synthesis of water was first observed by Davy (Phil. Trans. 1817; 97, 45, 77) in the case of platinum, and has been the subject of so many investigations that its adequate discussion here would be impossible, and properly belongs to the general consideration of catalytic action.

The energy change involved in these reactions is expressed by the heat of formation of water for which the chief data are given below.

$x=68,310$. Ice calorimeter; const. pressure, $t=0^\circ$ (Schuller and Wartha, Wied. Ann. 1877, 2, 381).

68,390. Burning at const. pressure, $t=18^\circ$ in 15° calories (Thomsen, Thermochem. Untersuch. 2, 45).

68,400. Burnt in bomb; calc. to const. pressure at $t=17^\circ$ in 15° cal. (Mixer, Silliman's J. 1903, (4), 16, 214).

68,380. Mean result of critical recalculation of foregoing, at 18° and const. pressure, in 15° cal. (Roth, Zeitsch. f. Elektrochem. 1920, 26, 1, 288).

Water is decomposed by the passage of an electric current, but owing to its very low conductivity the extent of the decomposition is very small with pure water. In practice, the electrolytic decomposition of water so-called, is effected by the electrolysis of aqueous solutions of electrolytes, and according to the ionic hypothesis the production of one at least of the constituent gases at the electrodes is due to a secondary action of the discharged ions.

It has long been known that the passage of an electrical discharge through steam produces both decomposition and a sorting of the products apparently akin to electrolysis (Perrot, Compt. rend. 1858, 46, 180; 47, 359; Ann. Chim. 1861, [iii.] 61, 161; J. J. Thomson, Recent Researches in Electricity and Magnetism, Cambridge, 1893, 559). But both oxygen and hydrogen may appear at either or both electrodes according to the size and form of the discharge vessel, and it seems probable that the separation observed is due to effects of diffusion and gaseous flow and not to true electrolysis (Chapman and Liddbury, J. Chem. Soc. 1908, 81, 130; Holt and Hopkins, Phil. Mag. 1908, [vi.] 16, 92).

Oxidizing and reducing action.—It is sometimes

knowledge that water acts on many metals, usually forming a basic oxide and hydrogen. The alkali and alkaline earth metals react with cold water; glucinum (beryllium), magnesium, and many rare-earth metals react with water below its boiling-point; zinc, cadmium, tin, iron, cobalt, nickel, and chromium decompose steam at a red heat, and some other metals, e.g. copper and lead, react only at a white heat. Mercury, silver, gold, platinum, iridium, &c., do not react at all with water.

Whilst this is broadly true for ordinary distilled water and ordinary metals, some qualification is necessary.

The very detailed and critical study which has been made of the interaction of water and air upon iron shows clearly how greatly such actions are influenced by minute traces of impurity in either water or metal, and it has been proved that water has no action on magnesium below 100° if free from air (Roberts and Brown, *J. Amer. Chem. Soc.* 1903, 25, 801), and acts extremely slowly at ordinary temperatures with sodium amalgam if free from traces of hydrogen peroxide (Baker and Parker, *J. Chem. Soc.* 1913, 103, 2060). Therefore caution must be used in regarding the observed reactions with metals, especially at low temperatures, as those of pure water. It is known that in the wet oxidation of some metals, e.g. zinc, hydrogen peroxide is produced and appears to take part in the reaction (*see e.g. Smith, J. Chem. Soc.* 1906, 89, 479).

Water can also oxidise many non-metals. Silicon is attacked by water in glass vessels at 100°, but the action is probably due to dissolved alkali (Moissan and Siemens, *J. Chem. Soc.* 1904, A. ii. 398) and occurs with pure water only at a higher temperature. Reaction of steam with carbon begins at about 850° (Farup, *Zeitsch. anorg. Chem.* 1906, 50, 276), and at higher temperatures proceeds according to the equations $C + H_2O \rightarrow CO + H_2$; $C + 2H_2O \rightarrow CO_2 + 2H_2$ with a reversible secondary reaction $CO_2 + H_2 \rightleftharpoons CO + H_2O$ (*see Gautier, Compt. rend.* 1906, 142, 1382). It is of great importance in the manufacture of producer-gas and water-gas (*q.v.*). Boron at a red heat similarly yields with steam boric oxide and hydrogen. At 2000° even nitrogen is oxidised by steam with the production of nitric oxide and hydrogen, $N_2 + 2H_2O \rightleftharpoons 2NO + H_2$, the mixture at equilibrium containing about 0.5 p.c. by volume of NO (Tower, *J. Amer. Chem. Soc.* 1905, 27, 1209).

Some of the lower oxides of metals, e.g. MnO, UO_2 , CrO , or compounds derived therefrom, e.g. potassium cobaltocyanide $K_3Co(CN)_6$, and molybdenous chloride Mo_2Cl_6 , are oxidised by water with liberation of hydrogen.

Thus the oxidising action of water is pronounced at high temperatures and occurs at low temperatures with powerful reducing agents.

Towards some non-metals, notably the halogens, water acts as a reducing agent, forming the non-metallic hydride and free oxygen. This action occurs with sulphur and phosphorus, but the oxygen simultaneously forms the non-metallic oxide. Thus with sulphur above 100° the reaction is represented by the equation $2H_2O + 3S \rightleftharpoons 2H_2S + SO_2$, though, of course,

equilibrium is reached at low concentrations of H_2S and SO_2 .

Hydrolysis.—Under this heading are included many of the most important and characteristic reactions of water.

The typical case is the hydrolysis of non-metallic chlorides, e.g. PCl_3 , PCl_5 , BCl_3 , $SiCl_4$, &c., to form hydrogen chloride and the hydroxy acid of the non-metal, e.g.

$BCl_3 + 3H_2O \rightarrow 3HCl + B(OH)_3$. Similar reactions occur with the corresponding bromides and iodides, and their irreversible character constitutes an important distinguishing characteristic of non-metallic elements. The one outstanding exception to this rule is the case of the halides of carbon, e.g. CCl_4 , $CBBr_4$, $C_2H_5Br_2$, &c., which are not hydrolysed by water to any appreciable extent at ordinary temperatures.

A similar, but reversible hydrolysis occurs to a greater or less extent with many metallic halides. The chlorides of bismuth and antimony are extensively hydrolysed in cold dilute aqueous solution, insoluble oxychlorides being precipitated: $BiCl_3 + H_2O \rightleftharpoons BiOCl + 2HCl$; $SbCl_3 + H_2O \rightleftharpoons SbOCl + 2HCl$, and the higher chlorides of lead, tin, titanium, &c., $PbCl_4$, $SnCl_4$, $TiCl_4$, are hydrolysed with the formation of the corresponding hydroxides, which in some cases remain in solution. Many other metallic salts, e.g. $MgCl_2$, $ZnCl_2$, $CuSO_4$, &c., are appreciably hydrolysed in their aqueous solutions, which thereby acquire an acid reaction. It is indeed only in the case of relatively few salts, those of strong bases such as the alkalis, with strong acids such as the halogen hydrides, nitric acid, sulphuric acid, perchloric acid, &c., that hydrolysis in solution is inappreciable. Just as the hydrolysis of the salts of weak bases with strong acids, e.g. $Al_2(SO_4)_3$, gives acid solutions, so that of salts of strong bases with weak acids, e.g. Na_2CO_3 , Na_2S , &c., causes their solution to have an alkaline reaction. It is frequently assumed that the neutral character of a solution of, say, potassium chloride, indicates an absence of hydrolysis, but this is by no means necessarily so. The neutrality of such a solution is quite compatible with extensive hydrolysis to yield equivalent amounts of acidic and basic solutes of the same type which, by the preponderance of one or other sort, give the basic or acidic character to solutions in which hydrolysis obviously occurs. This point is of importance to the theory of solutions (Vol. vi. p. 286).

The hydrolytic action of water increases with temperature, so that at a red-heat most metallic salts are completely hydrolysed by steam, e.g. $MgCl_2 + H_2O \rightarrow MgO + 2HCl$ (Moldenhauer, *Zeitsch. anorg. Chem.* 1906, 51, 369), and many, e.g. $NaCl$, which show no sign of hydrolysis in the cold, are partly decomposed.

Many binary compounds of metals with non-metals are readily and completely hydrolysed by water at ordinary temperatures, to produce the metallic hydroxide and the non-metallic hydride. The sulphides, selenides, nitrides, phosphides, and silicides of magnesium, glucinum, and aluminium are thus decomposed, and the hydrolysis of aluminium phosphide

of silicide is a convenient method for the preparation of phosphine or silicon hydride. Hydrolysis of the carbides is of special interest; some, e.g. aluminium or glucinum carbide, yield pure methane; others give various mixtures of hydrocarbons and hydrogen. The hydrolysis of calcium carbide to produce acetylene is the basis of a great industry, and that of nitrides, e.g. AlN , to produce ammonia has been employed in some processes for the fixation of atmospheric nitrogen.

Some binary compounds of non-metals, e.g. boron nitride, and the sulphides and selenides of boron and silicon, are similarly hydrolysable.

Hydrolysis of many metallic hydrides, e.g. LiH , CaH_2 , &c., yields the metallic hydroxide and hydrogen.

In organic chemistry innumerable hydrolytic reactions of importance are known, e.g. of organo-metallic compounds $\text{Zn}(\text{CH}_3)_2$, halides, esters, cyanides, &c.

Addition.—The direct addition reactions of water with basic and acidic oxides to form bases and acids occupy an intermediate position between hydrolytic action of the foregoing type and the so-called simple hydration discussed below.

Anhydrides of strong acids and bases, e.g. SO_3 , P_2O_5 , N_2O_5 , or Na_2O , CaO , Li_2O , &c., combine very readily with water; those of weaker acids and bases, e.g. B_2O_3 , SiO_2 , or ZnO , MgO , &c., react slowly or at higher temperatures. Data for the heat of hydration of typical basic oxides are given in Table 37.

TABLE 37.

HEATS OF HYDRATION OF OXIDES.

Typical examples of the heat of hydration of basic oxides, hydroxides and peroxides are given in the following table: the values given are in 15° gram-calories.

Heats of hydration	15° gram-calories	Reference
$\text{Li}_2\text{O} + \text{H}_2\text{O} \rightarrow 2\text{LiOH}$	14,400	1

This type of hydration leads to a profound change in the properties of the compound, and it is generally held that the water loses its character as such and enters into the constitution of the product in the form of hydroxyl groups. Such addition, therefore, resembles hydrolysis, save that one product only results.

Hydration.—The union of water with substances to form hydrates, as distinct from hydrolysis, is characterised by the slightness of its effect upon the physical and chemical

properties of the original substance. This is especially well seen where a compound forms a series of hydrates, e.g. FeCl_3 , Na_2CO_3 , CuSO_4 , as these differ from each other only slightly in colour, solubility, &c., and not at all in chemical properties.

It is the practice to confine the term *hydrate* to compounds in which water is present in fixed and simple molecular proportions; this, however, is an arbitrary rule. We have practically no evidence as to the manner in which

water of hydration (water of crystallisation) is held in the molecule. We know simply that water is evolved from hydrates, usually at comparatively low temperatures, that it is not directly and necessarily concerned in the most characteristic reactions of the hydrated substance, and that it can frequently be replaced molecule for molecule by other solvents, e.g. ether or alcohol, with a minimal change in the character of the hydrate.

The ease with which water is expelled from hydrates is illustrated by its liberation by simple grinding (Gillette, Chem. News, 1911, 104, 313), and in one recorded case by the action of light (McKee and Berkheiser, Amer. Chem. J. 1908, 40, 303). It has been suggested that hydrates may retain some water in solid solution (Richards, J. Amer. Chem. Soc. 1911, 33, 888).

Water of crystallisation has many of the properties of free water. It acts like free water upon calcium carbide (Masson, J. Chem. Soc. 1910, 97, 851) and upon some metals, e.g. magnesium (Michailenko and Mushinsky, J. Russ. Phys. Chem. Soc. 1912, 44, 181). It exhibits the same infra-red absorption bands as water (Schaefer and Scherbert, Ann. Physik. 1916, [iv], 50, 339).

Water can pass through solid plates of crystalline hydrates (Baker and Adams, J. Chem. Soc. 1911, 99, 597) by a process apparently resembling its diffusion through solutions.

Hydrated salts are curiously akin to the solutions from which they form. Where the colour of an anhydrous salt differs from that of its solution, e.g. CuSO_4 , CoCl_2 , CuBr_2 , CuCl_2 , &c., the colour of the crystalline hydrate is usually that of the solution. Hydrates exhibit a definite vapour tension of water; hence, on the kinetic theory, water molecules must pass freely in and out of the crystal space lattice as they do in and out of a solution. If the pressure of water vapour above the hydrate is less than its vapour tension, the hydrate loses water and *effloresces*. Conversely, it absorbs water and may *deliquesce*.

When a salt, capable of forming several hydrates (typically $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, which can yield $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$, $\text{CuSO}_4 \cdot \text{H}_2\text{O}$ and CuSO_4) is in equilibrium with its vapour in a closed space, and water is slowly but continually removed, the pressure of aqueous vapour over the hydrate remains constant until the whole is converted to the next lower hydrate, when the vapour pressure *suddenly* drops to that characteristic of the second hydrate and maintains that

value until conversion to the third hydrate is complete. This step by step transformation, readily interpreted in terms of the phase-rule, affords a means of detecting the existence of hydrates.

If during dehydration the vapour pressure be plotted against the percentage of water in the residual solid, the existence of a hydrate will be evidenced by a flat 'platform' on the curve; a continuous curve indicates the absence of definite hydrates.

Care must be exercised in applying this method, because there is frequently a delay, or period of induction, in the rise of the vapour pressure to the value characteristic of the temperature (Cumming, *Trans. Chem. Soc.* 1910, 97, 593; Partington, *ibid.* 1911, 99, 466; Ephraim and Millmann, *Ber.* 1917, 50, 539; Ephraim and Wagner, *Ber.* 1917, 50, 1068).

Indeed, Faraday showed (*Pogg. Ann.* 1834, 33, 186) that whereas hydrated sodium carbonate, sodium hydrogen phosphate, and sodium sulphate readily effloresce in air, perfect crystals of these salts may be kept in air for years without change. Inoculation with the lower hydrate at once causes the vapour pressure to assume its normal value. The period of induction in dehydration receives a rational explanation if we consider that the minute particles of the second phase formed at first by dehydration have, like small drops of water, an abnormally high vapour pressure (Rae, *J. Chem. Soc.* 1916, 109, 1229; see Pavlov, *J. Russ. Phys. Chem. Soc.* 1909, 41, 679).

Table 37 contains data for the thermal effect of several typical hydration reactions. Table 38 gives the equilibrium pressure of water vapour, in mm. of mercury, at 25° over a few of the more important crystalline hydrated salts, when in equilibrium with a lower hydrate or the anhydrous salt.

Solution and ionisation.—Water is, *par excellence*, the solvent. It has been argued that all substances are soluble in water, but this is not proven. Most salts and compounds usually classed as insoluble, e.g. silver chloride, glass, silica, are well known to have a small, but definite, solubility in water. The great majority of solids and liquids, and all known gases, are distinctly soluble, and some very soluble, in it.

There is much reason to believe that the solvent power of water and its pre-eminence as an ionising solvent are both due to chemical action between solvent and solute of the kind considered under hydrolysis and hydration.

An overwhelming mass of real evidence exists that substances dissolved in water are intimately associated, one had better say combined, with water or 'solvated' (see, for a list of references, Dhar, *Zeitsch. Elektrochem.* 1914, 20, 67; and for a critical review of earlier work, Washburn, *Hydrates in Solution*, *Tech. Quart.* 1908, 21, 360; as examples of more recent evidence, see e.g. Schaeffer, Paulus and H. C. Jones, *Phys. Zeitsch.* 1914, 15, 447; Philip and Bramley, *J. Chem. Soc.* 1915, 107, 371, 1637; Kornfeld, *Monatsh.* 1915, 36, 865; Faraday, *Trans. Faraday Soc.* 1917, 13, 123; Smith, Landa and Bouman, *Proc. K. Akad. Wetensch. Amsterdam*, 1921, 23, 969, and some

chemists have preferred to interpret all solution phenomena in terms of such compounds, even going so far as to regard the whole of the solvent as being combined with the solute (Kahlenberg, *Trans. Faraday Soc.* 1905, 1, 42).

On the other hand, much work adduced as evidence for solvation is unconvincing and contradictory. Kendall has remarked: "In the system $H_2SO_4-H_2O$, for instance, as many as 102 different hydrates have been 'discovered,' ranging in composition from $36H_2SO_4 \cdot H_2O$ to $H_2SO_4 \cdot 4950H_2O$. Few of these have been encountered twice by independent investigators, the opportunity for originality being almost unlimited." Thus many chemists have supported the original view of Ostwald and van't Hoff, which regards the solvent simply as a dispersive medium, enabling the solute to behave as if alone and in a gaseous state (see *Brit. Association Report*, 1890, 60, 311-328).

But the 'solvate' theory, rejecting the conception of ionisation altogether (see e.g. Armstrong and Worley, *Proc. Roy. Soc.* 1912, 87 A, 604), fails to explain in any satisfactory manner the mechanism of conduction in electrolytes, whilst the strict ionic theory equally fails to explain why and how ionic dissociation occurs.

It has been generally recognised by those who admit the existence of ions, that the ions in solution are hydrated (see Arrhenius, *Theories of Solutions*, pp. 184-195), and it has been pointed out that the rival 'solvate' and 'ionic' theories are in reality not irreconcilable but supplementary (Walker, *Brit. Association Report*, 1911, 81, 356).

There is, in fact, an intimate and general connection between ionisation and compound formation in solutions, and Kendall and Boege have strongly advocated the hypothesis that ionisation is preceded by, and is a consequence of, the formation of such compounds (Kendall and Boege, *J. Amer. Chem. Soc.* 1917, 39, 2323; this paper contains a detailed discussion of the hypothesis and numerous references to the literature, and should be consulted; the same idea had been indicated by others, to whom reference is made in the above paper, and was formulated with some precision by Bogorodski, *J. Russ. Phys. Chem. Soc.* 1914, 46, 1716).

Experiments with tetraethyl-ammonium iodide in a large number of solvents have shown that conductivity of solutions is fundamentally related to the dielectric constant and to the state of unsaturation of the simple molecules of the solvent (Walden, *Zeitsch. physikal. Chem.* 1903, 46, 103; 1906, 54, 129; H. C. Jones, *Amer. Chem. J.* 1901, 25, 232). These properties, as might be anticipated from their general parallelism, have a causal relationship (Thomson, *Phil. Mag.* 1914, [vi.] 27, 757; Lewis, *J. Amer. Chem. Soc.* 1913, 35, 1443; 1916, 38, 762).

Unsaturation implies the presence in the molecule of electrons which are free to move under the influence of an electric field. The simple water molecule (H_2O) contains two doublets, as in the formula $H^+ \cdots O^- \cdots H^+$; and the six free electrons of the oxygen atom will move into such positions as enable them to exert a maximum attractive force upon the

positive parts of these doublets, so that an unequal distribution of electric charges will result. By proximity of two such molecules this unequal distribution is accentuated and may lead to the formation of associated molecules, possessing a still larger electrostatic moment, in which the constraints are correspondingly weakened. Further association can occur with enhancement of these effects.

Great attractive forces are exerted by such associated molecules upon any solute RX ; these forces are cumulative as the molecules come into closer proximity, and can evidently lead to the formation of complexes of the type $R(H_2O)_n-X$, in which the constraints upon the electrons are still further weakened. Such complexes are much less stable than the simple component molecules and dissociable at any point, and it is thus possible to see how hydration may cause ionisation.

The essential probability of this theory is illustrated by the case of aqueous hydrochloric acid. Both hydrogen chloride and water when pure are almost non-conductors (Kohlrausch and Heydweiller, *Zeitsch. physikal. Chem.* 1894, 14, 326; Steele, McIntosh and Archibald, *ibid.* 1906, 55, 148); both contain unsaturated atoms in the simple molecule and are in consequence associated; both have high dielectric constants. When mixed they constitute a good electrolyte.

In contrast with the older ionic hypothesis, Kendall's theory permits us to regard the ionisation and conductivity as due to both constituents of the solution. Complex molecules $(H_2O)_2(HCl)$, are formed and dissociate to yield positively and negatively charged radicals. Taking the simplest case these would be either $(Cl-H_2O)^-$ and $(H-H_2O)^+$ or $(HCl-OH)^-$ and $(HCl-H)^+$, and on inspection these two alternatives are seen to be the same thing. The complex $(H_2OCl)^-$ may be regarded either as a hydrated chloride ion or a solvated hydroxyl ion.

The following table shows the degree of dissociation of pure water at various temperatures from 0° – 50° ; α being the weight in grms. of hydrogen ion in 1 c.c. of water at the stated temperature.

Temp.	$\alpha \times 10^{10}$
0°	0.36
2°	0.40
10°	0.57
18°	0.80
26°	1.10
34°	1.45
42°	1.91
50°	2.44

(Kohlrausch and Heydweiller, *Wied. Ann.* 1894, 53, 234; *Zeitsch. physikal. Chem.* 1894, 14, 330; the numbers are in substantial agreement with the indirect measurements of Arrhenius, *Zeitsch. physikal. Chem.* 1893, 11, 823; Nernst, *ibid.* 1894, 14, 155; Lorenz and Nehl, *ibid.* 1909, 66, 748; Noyes and Kato, *ibid.* 1910, 73, 20; Dolezalek, *Zeitsch. Elektrochem.* 1899, 5, 536; Kanolt, *J. Amer. Chem. Soc.* 1907, 29, 1414; Lewis, Brighton and Sebastian, *ibid.* 1917, 39, 2260; Lunden, *J. Chem. Phys.* 1907, 5, 589; Heydweiller, *Ann. Physik.* 1909, [iv.] 23, 511).

The heat of formation of water from its ions is +14,700 gm. cal. per gm. mol. at $0^\circ C$, the value at other temperatures t , being given by +14,700–50 t . This is the most probable value derived from a number of researches by different methods, as follows:

1. From the heat of neutralisation of strong acids by strong bases (Wörmann, *Ann. Physik.* 1905, [iv.] 18, 793; Heydweiller, *Ann. Physik.* 1909, [iv.] 23, 503; Thomsen, *Thermochem. Untersuch.* 1882; Müller, *Bull. Soc. chim.* 1918, [iv.] 23, 8; Müller and Bauer, *J. Chim. Phys.* 1904, 2, 457).

2. From the change of conductivity of pure water with change of temperature; calculated by van't Hoff from the data of Kohlrausch and Heydweiller.

3. From the variation with temperature of degree of hydrolysis of salts (Lunden, *J. Chem. Phys.* 1907, 5, 145, 574; 1908, 6, 6, 81; Noyes, *Carnegie Inst. Publ.* 1907, No. 63).
H. V. A. B.

Water in its Economic and Sanitary Relations, Drinking Water.

Water for Domestic Supply.

Water is absolutely indispensable to both animal and vegetable life; it is the cause of many of the most striking phenomena in nature, and is employed for countless purposes by man. Its distribution is as wide as that of the air itself whilst its amount on the earth is enormously greater. In an absolutely pure state it is never met with in nature. The impurities in natural water are derived from the materials—solid, liquid, or gaseous—with which it comes in contact, and they may be present either in suspension or in solution or in both. Inasmuch, therefore, as the interest attaching to different waters depends upon the impurities they contain, and these are dependent upon the matters with which they have been in contact, it is most convenient to classify waters according to their origin.

1. *Rain-water, snow, hail, dew, and hoar-frost.* All these forms of water are obtained by the condensation of the aqueous vapour which is invariably present in the air. The amount of aqueous vapour which can be contained in a given volume of air is solely dependent upon the temperature. If the atmosphere has become saturated with aqueous vapour at any given temperature and is cooled below that temperature, the excess of aqueous vapour will condense, according to circumstances, as rain, hail, snow, mist, dew, or hoar-frost. This condensation is promoted by the presence of dust and electrically charged particles. All these forms of water having been only in contact with the air and not with the earth are characterised by the small proportion of solid matter which they contain, although the amount found, especially in the vicinity of towns, is often considerably greater than would be anticipated, and the rain-water falling in the neighbourhood of the sea is often mixed to a considerable extent with sea-spray, which with favourable winds is carried many miles inland. In the following table are recorded the maximum, minimum, and average proportions of several ingredients in samples of rain-water collected at Rothamsted and elsewhere, expressed in parts per 100,000—

	Total solid impurity	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Chlorine	Hardness
Minimum	0.62	0.021	0.003	0.005	0	0	0
Maximum	8.68	0.372	0.121	0.155	0.044	1.65	1.7
Average	3.42	0.095	0.021	0.049	0.007	0.33	0.5
Rain-water collected at Land's End, Cornwall, Jan. 2, 1873	42.80	0.131	0.034	0	0.020	21.8	10.0
Rain-water collected near Hyde Park, London, Nov. 8, 1873	2.76	0.383	0.040	0.210	0.008	0.5	1.1

It is thus seen that the composition of rain-water, even in the open country, is liable to great fluctuations, and that the amount of impurity, both mineral and organic, is occasionally surprisingly large. The amount

of organic impurity in dew and hoar-frost is still greater owing to these forms of water being condensed out of the lowest and most-contaminated couches of the atmosphere. Thus—

SEVEN SAMPLES OF DEW AND HOAR-FROST, ROTHAMSTED, 1869 AND 1870.

(Results of Analysis expressed in parts per 100,000.)

	Total solids	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Chlorine	Hardness
Minimum	2.64	0.195	0.026	0.130	0	0.35	1.3
Maximum	8.00	0.450	0.196	0.280	0.050	0.80	2.5
Average	4.87	0.264	0.076	0.198	0.023	0.53	1.9

Two other impurities, not referred to above, which are generally present in the rain-water and snow of towns are sulphurous and sulphuric acids derived from the combustion of coal. Angus Smith found in the rain-water of London 3.05, of Liverpool 3.96, in that of Manchester 4.48, and in that of Glasgow 7.02 parts of sulphuric acid per 100,000, to a considerable extent in the free state. Sendtner found freshly-fallen snow in Munich to contain 0.7 part sulphuric acid (SO_3) per 100,000, on the following day 1.76 parts, after 10 days 6.22 parts, and after 16 days 9.18 parts. The presence of this free acid in the rain-water of towns is, of course, not only detrimental to vegetation, but also to sculptures and buildings in which marble or limestone are employed. The proportion of ammonia increases in the snow after lying on the ground (Wagner, *Technologie*, 308).

2. *Upland surface water* most nearly approaches in composition to that of the atmospheric waters dealt with in the last section. It is, in fact, rain-water which has undergone minimum contact with the earth, although in consequence of its solvent action even this contact is sufficient to impart to the water in many cases such proportions of dissolved matter as are never found in rain-water. The amount and nature of these ingredients depend, of course, mainly upon the kind of soil over which the water has travelled, and consequently it becomes convenient to sub-divide this class according to the geological character of the ground from which the upland surface water has been obtained.

In the tables on p. 370 are recorded the maximum, minimum, and average amounts of impurity found in the examination of a large series of samples of waters principally derived from land not under cultivation, so as to represent the characters naturally acquired by water passing over the various geological formations.

The tables (I. and II.) show that upland surface waters generally contain a considerable amount of dissolved matters only when they are derived from calcareous strata. The organic matter is subject to great variation, but in every case contains only a very small proportion of nitrogen in comparison with the carbon, indicating that the organic substances present are of vegetable origin, which is further attested by the almost entire absence of ammonia, nitrates, and nitrites, all of which, when present in amount beyond that in which they occur in rain-water, are nearly exclusively derived from the decomposition of animal matters. The chlorine is also low, the upland gathering grounds being generally beyond the reach of sea-spray and not receiving the liquid excrements of animals, which are particularly rich in chlorides, whilst from their mere surface contact with the soil they have not extracted any considerable quantities of the salts present in the latter, as is the case with spring- and well-water.

3. *Surface water derived from cultivated land*.—This includes the great body of river-waters, inasmuch as practically all streams flow through and receive accessions from land under cultivation before reaching the sea. The water

¹ Owing to the compact nature of the limestone in these old formations, the hardness is very moderate.² Hardness not excessive, but large amount of organic matter (peaty), rendering the waters coloured and unpalatable.³ Of very variable character; generally of only moderate hardness, but containing much peaty matter, and hence coloured and unpalatable.⁴ Slightly turbid.⁵ Slightly turbid. Owing to the porous nature of Oolite formation, surface water is very rare.

position of such waters is very varied, depending upon local circumstances, and being liable to great fluctuations at different seasons of the year. This group may be conveniently divided into two sub-groups, according as the water

is derived from calcareous or non-calcareous districts. The following results of analyses of British waters of this description are compiled from the Sixth Report of the Rivers Commission, 1874:—

SURFACE WATERS FROM CULTIVATED LAND.

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
(a) Water from non-calcareous districts. ¹										
Maximum	18.10	1.124	0.112	0.056	0.258	0.393	2.80	4.6	8.0	10.1
Minimum	5.26	0.125	0 ²	0	0	0.017	0.70	0	1.8	2.1
Average (31 samples)	9.52	0.276	0.034	0.007	0.089	0.128	1.49	0.6	4.3	4.9
(b) Water from calcareous districts. ³										
Maximum	110.40	1.338	0.307	0.030	1.005	1.096	12.75	26.3	42.1	67.3
Minimum	13.22	0.069	0.009	0	0	0.033	0.54	0	2.1	7.8
Average (144 samples)	30.08	0.268	0.053	0.005	0.257	0.314	2.24	12.4	8.2	20.6

¹ Usually turbid, organic matter generally moderate in amount, but partially of animal origin.

² This result is extremely improbable, more especially as the particular water in question (a sample of the water supplied to Bury and Radcliffe, Lancashire) contained 0.229 organic carbon, 0.032 ammonia, and 0.066 nitrogen as nitrates and nitrites.

³ Generally turbid, the organic matter is much the same in amount as in the water from non-calcareous districts, but generally more nitrogenous, in consequence of calcareous soils being usually under higher cultivation than non-calcareous ones. The total combined nitrogen is also for the same reason considerably greater, and the hardness is, of course, very much higher.

In connection with the effect of cultivated land upon the water with which it comes in contact, it is instructive to note the nature of the water which drains from such land, as this throws light upon the composition of subterranean waters (from springs and wells), which will be considered below.

In the following table is recorded the composition of the water obtained from drain-pipes placed from 18 ins. to 5 ft. below a plot of land at Rothamsted which had remained both unmanured and uncropped for a period of 11-15 years:—

COMPOSITION OF WATER FROM LAND UNMANURED AND UNCROPPED FOR ELEVEN TO FIFTEEN YEARS.¹ (6th Rep. Riv. Com. p. 62.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum	63.28	0.235	0.116	0.026	4.936	4.981	3.80	7.2	11.3	16.5
Minimum	18.00	0.096	0.026	0	0.607	0.654	0.60	0.3	3.3	3.6
Average (15 samples distributed over four years)	32.06	0.154	0.053	0.006	2.195	2.253	1.65	4.1	8.5	12.6

¹ The samples varied from clear to turbid.

It will be seen that the conversion of the original nitrogenous organic matter in the soil into mineral products is a very slow process, large quantities of nitrates being still present in the drainage waters after the lapse of so many years.

It is interesting to compare with the above the composition of the water draining from a plot of land unmanured for 16-21 years, but continuously bearing an annual wheat crop during that time:—

COMPOSITION OF WATER FROM LAND UNMANURED FOR SIXTEEN TO TWENTY-ONE YEARS, BUT CONTINUOUSLY BEARING WHEAT CROPS. (6th Rep. Riv. Com. p. 80.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . . .	48.40	0.242	0.058	0.006	2.268	—	3.80	14.1	22.4	32.7
Minimum . . .	13.80	0.099	0.010	0	0	—	0.80	8.9	3.9	13.5
Average (11 samples distributed over five years) . . .	24.96	0.170	0.034	0.002	0.645	—	1.37	10.8	8.4	19.2

As might have been anticipated, the proportions of ammonia and nitrates finding their way into the drainage water in this case were much less, and in the summer months during the growth of the crop the amount of this mineral nitrogen found in the drainage water was practically nil.

We will, in the next place, compare with the above the composition of the drainage water from land which had been manured annually with 14 tons of farmyard manure per acre over a period of 24-29 years, and bearing wheat continuously during that time:—

COMPOSITION OF DRAINAGE WATER FROM LAND MANURED WITH 14 TONS FARMYARD MANURE PER ACRE FOR TWENTY-FOUR TO TWENTY-NINE YEARS. (6th Rep. Riv. Com. p. 58.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . . .	51.20	1.243	0.335	0.052	2.592	2.754	3.35	12.1	20.6	32.1
Minimum . . .	14.00	0.181	0.036	0	0.082	0.130	0.60	1.4	5.4	8.7
Average (13 samples over five years) . . .	25.90	0.519	0.115	0.009	0.528	0.665	1.30	6.8	8.6	15.4

Thus the difference between the drainage waters from the unmanured and manured land is not nearly so great as might have been expected, being principally confined to the larger proportion of organic matter found in the latter.

The above results may be compared with

those obtained in the analysis of a number of samples of the drainage water from sewage farms, in all of which the town sewage is, or was, applied to land, with the double object of purifying the sewage and deriving a profit out of the crops raised. Thus:—

COMPOSITION OF DRAINAGE WATER FROM SEWAGE FARMS. (6th Rep. Riv. Com. pp. 55-57.)

(Results of Analysis expressed in parts per 100,000.)

Description	Total solid matters	Organic carbon	Organic nitrogen	Ammonia	Nitrogen as nitrates and nitrites	Total combined nitrogen	Chlorine	Hardness		
								Temporary	Permanent	Total
Maximum . . .	103.00	2.160	0.517	1.366	6.499	6.833	13.40	36.9	39.3	56.6
Minimum . . .	18.60	0.108	0.034	0.005	0	0.069	2.15	0	3.9	3.9
Average (72 samples) . . .	64.02	0.982	0.191	0.388	0.756	1.266	6.36	17.6	15.4	23.0

It will be seen that the drainage water from sewage farms is generally richer in organic and inorganic impurities than the water draining from manured or unmanured land, the passage of the water through the ground being in the latter case a much slower one, and thus allowing time for more perfect purification by soil and

plants. Occasionally, as indicated by the above minimum results, the drainage water from sewage farms is remarkably free from impurities. A much purer drainage water is often yielded in the intermittent downward filtration of sewage through suitable land.

The knowledge thus gained of the composition

SHALLOW WELL WATERS.

(Results of Analysis expressed in parts per 100,000.)

testify to the water having previously been in contact with nitrogenous organic matter which has subsequently undergone destruction. In shallow well waters, even when the organic matter is only small in amount, it is generally highly nitrogenous, pointing to its probable animal origin, and in some exceptional cases the organic nitrogen found is actually in excess of the carbon. These waters, which are generally suspicious from the presence of mineral nitrogen, become in the highest degree dangerous when the proportion of organic matter is large.

5. *Deep well waters*.—It is convenient to distinguish for sanitary purposes between waters which are obtained from comparatively shallow wells and those which are derived from wells, say, upwards of 100 ft. in depth, and sometimes reaching to the distance of more than 1000 ft. below the surface of the earth. The presumption is that waters obtained from such a depth have undergone perfect filtration through porous strata, and consequently it is not usual to view the evidence of previous contact with animal matters afforded by the presence of mineral nitrogen with so much suspicion as in the case of the waters from the shallower wells. The great efficiency of the filtration which most of these deep well waters have undergone is attested both by their freedom from organic matter, and from every kind of suspended material, whether organic or inorganic. In consequence of the excellent water obtainable from such deep wells, they have been multiplied greatly during past years, so that at the present time not only are many towns (including a part of London) and villages supplied from this source, but also nearly all larger breweries and many private establishments. In some cases these deep wells are of the kind known as 'Artesian' (from Artois, in France, where they were probably first employed); that is to say, on reaching the water-bearing stratum the water rises to the level or even considerably above the level of the ground, due to the underground water being confined under pressure beneath an impervious stratum of clay or the like, and through the outcrop of the water-bearing stratum being at a considerably higher altitude than the point at which the boring has been made. Thus, in the London basin, 'Artesian wells' are obtained by sinking through the London clay into the chalk beneath, which has its outcrop at considerable altitudes in the chalk hills on the north and south of the Thames valley. Owing to the large abstraction from such water-bearing strata, the water of many wells which formerly rose to the surface has now to be pumped. In the majority of deep wells the water does not rise nearly to the surface, and the pumps have often to be placed at considerable depths in the shaft. It is usual to line these wells with closely-fitting iron cylinders, in order to exclude surface water, as unless this is done the deep wells may become as objectionable and dangerous as shallow ones.

The preceding tables afford a survey of the general character of the deep well waters obtained in Great Britain. In nearly all the samples of which the maximum, minimum, and average results are given, it may be taken that the wells are unpolluted by surface water, but for the sake of comparison there are appended

to most of the sections analyses of deep well waters from the same strata in which pollution by surface or imperfectly-filtered water is highly probable.

These results demonstrate the great superiority from a chemical point of view of the subterranean waters obtained at great depths to those derived from shallow wells. Indeed, these deep well waters are, as regards organic matter, amongst the purest to be found in nature, and hence, unless extremely hard, are of the best quality for drinking purposes.

Closely associated with these deep well waters is the next group of spring waters.

6. *Spring water*.—In the following table is given the composition of, presumably unpolluted, British spring waters arranged according to the geological nature of the ground from which they are derived, whilst for the sake of comparison the composition of probably polluted spring waters from the same geological source is in many cases appended.

7. *Mineral spring waters*.—Many spring waters possess marked medicinal properties in consequence of the materials they hold in solution. Until the discovery of radium it was generally supposed by chemists that the therapeutic value of such waters containing only an insignificant amount of mineral matter must be imaginary, but it is now known that some of these, such as the waters of Bath and Buxton, are pronouncedly radioactive, and it is generally accepted at the present time that the old-established efficacy of these waters in the treatment of gout and rheumatism is due to their content of radioactive material (*see* Nature, 1911, 86, 157). Indeed, radium-salt is now much employed for the artificial production of radioactive water for medicinal purposes. An immense number of mineral waters are in use, and have been submitted to careful analysis; a very extensive collection of such analyses is to be found in Raspe's *Heilquellen Analysen*, Dresden, 1885.

These mineral waters are conveniently classified by Hermann Weber (Quain's Dictionary of Medicine), according to the ingredients which characterise them, into—(1) Simple thermal waters; (2) common salt or muriated saline waters; (3) alkaline waters; (4) sulphated saline waters; (5) iron or chalybeate waters; (6) sulphur waters; (7) earthy and calcareous waters.

(1) *The simple thermal waters*, whilst containing only a moderate proportion of dissolved solids, are characterised by a high temperature, from 27°–65°, and sometimes by the presence of an unusually large proportion of nitrogen, which is now known to be mixed with appreciable quantities of helium. Doubtless the medicinal reputation of most, if not all, of these waters depends on their radioactivity. The principal springs of this class are: Panticoesa, Leukerbad, Bormio, Gastein, Pfäfers, Johannisbad, Ragatz, Wildbad, Plombières, Buxton, Bath, Looe, Teplitz, Schlangenbad, &c.

(2) *Common salt or muriated saline waters* contain sodium chloride as the principal constituent, although this also occurs often in large quantity in many of the other classes of mineral waters. These salt waters or brines are very common in almost all countries. Some of the

SPRING WATER. (6th Rep. Riv. Com. p. 107.)

¹ Water supply of Western-super-Mare; these exceptionally high results doubtless due to access of sea water.

principal ones in England are: Droitwich, Nantwich, Middlewich, Woodhall, and Harrogate; Leamington and Cheltenham along with sodium sulphate. In Germany: Kissingen, Homburg, Nannheim, Kreunach, Soden, Pyrmont, Wiesbaden, Ischl, Kreuth, Baden-Baden, &c. In France: Bourbonne-les-Bains, Lamotte-les-Bains, Balaruc, Salins. In Italy: Castellamare, Ischia, Monte Catini, La Porretta. In Switzerland: Bex.

(3) *Alkaline waters* are characterised by the presence of sodium carbonate, almost always with more or less free carbon dioxide, and sometimes with a large quantity also of sodium chloride. Of the simply alkaline waters, there are—(a) *Hot*: Vichy, Neuenahr, Mont-Dore, Chaudesaigues, Nérès; (b) *Cold*: Apollinaris, Vals, Salsbrunn, Biliu, Wilhelmsquelle, Taunus, Marcollo; whilst the chief muriated alkaline waters are: (a) *Hot*: Ems, Royat, La Bourboule; and (b) *Cold*: Luhatschowitz, Selters, Gleichenberg, Rosbach, Vie-sur-Cère. Several of these, but especially La Bourboule and Mont-Dore, contain a marked proportion of arsenic.

(4) *Sulphated waters* contain either sodium or magnesium sulphate, or both, as the prominent ingredients, in some cases also associated with sodium carbonate and chloride. They are often called '*bitter waters*.' The chief simple sulphated waters are: Galthof, Pullna, Said-schutz, Sedlitz, Birmensdorf, Ivanda, Hunyadi Janos, Epsom, Aranjuez, Friedrichshall, Mergentheim; the two latter are also rich in chlorides. Weaker springs of the same kind are found at Leamington, Cheltenham, Scarborough, and at Purton Spa. Of alkaline sulphated waters there are: Carlsbad, Marienbad, Tarasp-Schule, Franzensbad, Elster, and Bertrich.

(5) *Iron or chalybeate waters* are those in which an unusual proportion of this element is present, either in otherwise comparatively pure water or associated with other mineral matters. Thus, of comparatively pure chalybeate waters, there are those of Schwalbach, Spa, Brückenaau, Schandau, Lieberwerda, Flinsberg, Freienwalde, Reccaro, Königswarth, Liebenstein, Altwasser, Alexisbad, Muskau, Tunbridge Wells, and some of the springs at Harrogate; whilst of waters in which the iron is associated with a considerable quantity of other salts, there are those of Aratap, Orezza, Pyrmont, Driburg, Rippoldsau, Grisebach, Antogost, Petersthal, Bocklet, St. Moritz, Reinerz, Godesberg, Cudowa, Imnan, and Santa Catarina.

(6) *Sulphur waters* are those containing appreciable quantities of either sulphuretted hydrogen or the sulphides of sodium, potassium, calcium, or magnesium. Some of the more important thermal sulphur waters are those of Eaux Chaudes, Cauterets, Saint Sauveur, Bagnères, Bagnères-de-Luchon, Ax, Escaldes, Le Vernet, Amélie-les-Bains, Uriage, Allevard, Aix-les-Bains, Aix-la-Chapelle, Baden (Austria), Baden (Switzerland), Lavey, Schinznach, Battaglia, and Abano in the Euganean Mountains, Panticosa, Mehadia, Helouan, near Cairo; whilst of cold sulphur springs there are those of Nilsen, Neundorf, Langenbrücken, Weilbach, Meisberg, Reutlingen, Engheim, Challes, Stachelberg, Hemsbach, Gurnigel, some of the Harrogate springs, Llandrindod, Builth, Moffat, Strathpeffer, Lischnyarna.

(7) *Barthy and calcareous waters* are characterised by the presence of large proportions of calcium carbonate and sulphate, and magnesium carbonate. Some of the more important are found at Wildungen, Lippespringe, Weissenburg, Contrexéville, Bagnères-de-Bigorre, St. Arnaud, Crausac, whilst the table waters of Cousan, St. Galmier, and Taunus are of the same character.

8. *Sea water*.—The ocean is a great evaporating-basin, which is constantly receiving waters, more or less impure, in the shape of rivers, whilst at the same time it is constantly losing pure water in the form of vapour, the impurities remaining behind and imparting to the sea its well-known saline character. This also distinguishes all lakes which are devoid of outlet, like the Dead Sea, Caspian, Aral, Great Salt Lake Utah, &c., in which the same process of concentration by evaporation is going on. As will be seen from the table on the next page, the composition of the ocean varies considerably in different places and at different depths, whilst land-locked seas, like the Mediterranean, Black Sea, and Baltic, present even still greater differences.

Thus in the vicinity of the poles the proportion of salt is less than near the equator; similarly, land-locked seas, such as the Black Sea and Baltic, which receive large rivers are less salt; whilst the Mediterranean in most places is more salt than the great oceans. Of salt lakes the Dead Sea is far more and the Caspian far less salt than the oceans. In addition to sodium chloride, the principal substances present in sea water are the sulphates and carbonates of calcium and magnesium, and salts of potassium, whilst in very minute quantities there are found also a number of others, amongst which may be mentioned bromides, iodides and fluorides, silica, phosphoric and nitric acids, iron, silver, gold, copper, lead, arsenic, zinc, cobalt, nickel, lithium, rubidium, and caesium.

The volume of gas dissolved in sea water is, according to Hunter (Chem. Soc. Trans. 1870, 20), only from 2.2 to 3.5 vols. in 100 vols. of water.

	CO ₂	O	N
	per cent.	per cent.	per cent.
2.2 vols. consisted of	28.62	21.94	49.44
3.5 " "	48.28	17.22	34.50

A very extensive examination of the composition of sea water was made in connection with the voyage of H.M.S. *Challenger*, and the elaborate report prepared thereon by Dittmar should be consulted for detailed information on this subject. From 77 complete analyses, the following numbers for the average composition of ocean-water salts are calculated:—

Average composition of ocean-water salts, in parts per 100 of total salts (Dittmar).

Chlorine	55.222
Bromine	0.1884
Sulphuric acid (SO ₄)	6.410
Carbonic acid (CO ₂)	0.152
Lime (CaO)	1.676
Magnesia (MgO)	2.209
Potash (K ₂ O)	1.232
Soda (Na ₂ O)	41.224
(Basic oxygen equivalent to the halogens)	(—12.422)

(Results of Analysis expressed in parts per 1000.)

The salinity of the ocean, expressed in parts of total salts per 1000 parts of sea-water, was found to vary between the following limits: Minimum (from the southern part of the Indian Ocean, south of 66° lat.), 33.01; maximum (from the middle of the North Atlantic, at about 23° lat.), 37.37.

As regards the carbon dioxide in sea water, Dittmar comes to the following conclusions: (1) Free carbonic acid in sea water is the exception; as a rule, the carbonic acid is less than the proportion corresponding to bicarbonate. (2) In surface waters the proportion of carbonic acid increases when the temperature falls, and *vice versa*. (3) Within equal ranges of temperature it seems to be lower in the surface water of the Pacific than it is in the surface water of the Atlantic Ocean.

Drinking Water. It has long been known that the palate is by no means a safe guide in the choice of drinking water, for although unpalatable waters are obviously unsuitable for drinking, palatable waters may contain materials capable of doing serious injury. It is now established beyond question that the diseases termed 'symiotic' are due to minute forms of life known as micro-organisms, and in a number of cases the specific forms responsible for such diseases have been discovered, identified, and studied. Of symiotic diseases there are two—Asiatic Cholera and Typhoid Fever—which are with certainty known to be propagated by drinking water, and in the case of these two diseases authorities are agreed as to the particular organisms to which they are due. The propagation unquestionably takes place through the excreta of persons suffering from these diseases gaining access to water which is afterwards used for drinking, whilst water contaminated with the sewage of healthy persons is generally believed to be capable of producing diarrhoea and other minor disturbances in those drinking it.

In selecting water for drinking purposes it is necessary, therefore, in the first instance, to make a careful inquiry as to the possibility of the water having been in contact with refuse animal matters, and if possible all waters open to such suspicion should be discarded. For the same reason it is of the first importance in the examination of water to discover what evidence, if any, there is of the water having been in contact with such refuse substances. In the present state of knowledge this is a difficult matter, as, although the results of chemical analysis frequently point to such contamination when on a sufficiently large scale, it is occasionally and indeed generally impossible to prove the negative. The bacteriological examination, on the other hand, is of extreme delicacy, but, inasmuch as we have at present no means of ascertaining whether the bacteria indicative of faecal contamination are derived from man or from the lower animals, the results obtained by this means, also, are often of restricted value from a hygienic point of view. It becomes, therefore, of the greater importance to make a thorough inspection of the source and to trace out the further history of the water, for unless this be done the results of the scientific examination may often receive an erroneous interpretation. As, however, it is comparatively rarely

that natural waters are to be met with which are absolutely above suspicion of any contamination with refuse animal matters, it is generally necessary to be satisfied with relative purity, and thus the examination, chemical and biological, of drinking waters becomes a matter of the highest importance and utility. The natural waters which can lay claim to the greatest degree of safety for drinking purposes are of two kinds.

1. Unpolluted surface waters (generally upland waters).

2. Naturally filtered waters (spring and deep well waters).

In the first case the waters, both by inspection and analysis, must bear no evidence of animal contamination, and this is generally only possible in the case of waters which are found at altitudes above that of human habitations. A number of our large towns are supplied with water of this kind, although the gathering-grounds do in most cases contain some houses, so that absolute freedom from sewage contamination cannot generally be guaranteed. In the table on p. 381 the chemical composition of some of these upland surface water supplies is recorded.

The majority of upland surface waters are either very soft or of only very moderate hardness, and as in many of these towns extensive manufactures are carried on, these supplies are not only valued because of their safety for drinking, but also on account of their fitness for industrial purposes. It should always be remembered, however, that these surface waters may at times receive more or less sewage contamination, and that the ova of animal parasites derived from the cattle grazing on the gathering-grounds may also be present, and that, therefore, to reduce these sources of danger to a minimum, it is highly desirable that such waters should be subjected to prolonged storage in reservoirs, followed by careful filtration through sand before delivery to the consumer.

In the second class of water its original purity is a matter of secondary consequence, the guarantee of safety resting upon the exhaustive process of filtration which the water has undergone in passing through porous strata of the earth's crust. This filtration effects, on the one hand, the more or less complete chemical purification of the water from organic substances, and, on the other hand, the mechanical removal of organised matters, such as bacteria and animal parasites. The most perfectly filtered waters of this kind are those obtained from springs and from deep wells, and, again, many of our towns are supplied with water of this kind—more especially from the Chalk, Greensand, Oolite, and New Red Sandstone formations, which constitute efficient filter beds. In the table on p. 382 is recorded the chemical composition of the water supplied to some of our towns from such sources.

Of other forms of drinking water we have river waters and shallow-well waters, upon both of which a very large portion of the population is dependent for domestic supply. Both of these classes of water are open to grave objections, and nearly all the best authenticated cases of the propagation of cholera and typhoid through drinking water have been traced to

shallow wells. There are, however, many potent influences tending to remove bacteria from water which, on a priori reasoning, would have been regarded as almost, if not wholly, inoperative. These causes are mainly the process of devitalisation which pathogenic bacteria undergo in natural, and more especially in surface waters, and the resistance offered by even a comparatively small thickness of soil or other porous material to the passage of micro-organisms. But although these causes are to be looked upon as tending to keep the evils which can result from contaminated drinking water within narrower limits than might have been anticipated, still the possibility of their failure must be constantly kept in view, and they must not be allowed to check the endeavour to substitute unimpeachable for suspicious sources of supply.

Every effort should be made to exclude avoidable sources of contamination, to select the best water which the source affords, and to submit it to the most effective purification available. The improvements which can thus be brought about in water supplies obtained from suspicious sources is conspicuously exemplified in the case of the London supply derived from the rivers Thames and Lea. Here, on the one hand, increasing vigilance has been exercised by the Thames and Lea Conservancy Boards in the exclusion of dangerous matters from the rivers and their tributaries, whilst on the other hand the authorities supplying water have removed their intakes to points on these streams above the most serious pollutions; by increasing their storage capacity they are enabled not only to

avoid drawing from the rivers in times of flood, but also to bring about a great amelioration in the quality of the water during its sojourn in the reservoirs, whilst by improving their filtering appliances they secure a more perfect purification of the water which they have abstracted. Thus the water supplied to London to-day is both chemically and hygienically very different from what it was 60 years ago, although still derived from the same streams, which in the ordinary course of events would be more polluted now than they were then.

Importance to be attributed to various ingredients of drinking water.—It is only possible here to give a brief account of the importance which is usually attributed to the several ingredients which are commonly determined in the analysis of drinking waters.

Dissolved gases.—The gases present in ordinary drinking waters are those of the atmosphere—oxygen, nitrogen, and carbon dioxide. Their quantitative determination is of little or no significance in connection with the quality of the water for drinking, excepting that through the absence of dissolved gases a water has the flat taste of that which has been recently boiled. It is sometimes supposed that the absence of a due proportion of dissolved oxygen in water is an indication of the presence of decomposing organic substances, but this can only be the case with surface waters, as the very purest subterranean waters are almost entirely destitute of it. In the following table the proportion of the several dissolved gases in different kinds of water is recorded :—

Gases dissolved in 100 cub. ins. of water	Rain-water	Cumberland mountain water	Loch Katrine water	Thames water	Deep chalk well water
	cub. ins.	cub. ins.	cub. ins.	cub. ins.	cub. ins.
Nitrogen	1.308	1.424	1.731	1.325	1.944
Oxygen	0.637	0.726	0.704	0.588	0.028
Carbon dioxide	0.128	0.281	0.113	4.021	5.520
	2.073	2.431	2.548	5.934	7.492

The large proportion of dissolved carbon dioxide in the Thames and deep chalk well water is mainly combined with calcium carbonate as bicarbonate.

Total solid residue.—It is only rarely that the amount of the residue left by a water on evaporation affords any evidence of its fitness for drinking. As a general rule, it may be stated that waters which contain very small residues are probably pure and unpolluted, but on the other hand many waters of organic purity contain large proportions of mineral matter in solution. It is impossible to assign limits to the proportion of mineral matter which may be present in water without interfering with its fitness for drinking, more especially as opinion is divided as to the influence of the several constituents on health (v. also *Hardness of water*). Nearly all the best drinking waters in the United Kingdom yield less than 50 parts of solid residue per 100,000, and most of them very considerably less. The use of waters yielding much larger residues is generally attended by the inconvenience which attends

their employment for general domestic purposes, in consequence of their unfitness for boilers and washing.

Organic matter.—As will be pointed out (under *Water analysis*), the accurate determination of the organic matter in water is attended with great difficulties, and none of the methods of analysis in use claims to effect more than a partial determination. Thus in the 'combustion process' the organic carbon and nitrogen are determined with more or less accuracy; in the alkaline permanganate process that portion of the organic nitrogen is discovered which is readily convertible into ammonia; whilst in the 'permanganate' or 'oxygen' process the proportion of permanganate destroyed by the organic matter is taken into account. Although it may be stated generally that the smaller the proportion of organic matter the more desirable is the water for drinking, of still greater importance is the determination of the origin of the organic matter present, whether animal or vegetable. The presence of vegetable matter is of comparatively little consequence

more especially as even small amounts interfere with the palatability of the water, what is known as a 'peaty taste' being imparted by any amount yielding much in excess of 0.2 part per 100,000 of organic carbon. Sometimes much light may be thrown on the origin of the organic matter in water by the proportion which the carbon and nitrogen exhibit towards each other, especially when this is considered in connection with the proportions of ammonia, nitrates, nitrites, and chlorine. Inasmuch as animal matter in general contains a much higher proportion of nitrogen to carbon than does vegetable matter, it follows that the higher the ratio of nitrogen to carbon in the organic matter present in a sample of water, the more probability is there, *ceteris paribus*, of its being derived from animal sources and *vice versa*. The possibility of such diagnosis, however, is considerably limited by the fact that in the oxidation of peaty matter the organic carbon disappears much more rapidly than the nitrogen; whilst, on the other hand, in the oxidation of animal matter there is conversely a tendency for the organic carbon to become concentrated, thus leading to a simulation of animal matter in the case of vegetable, and a simulation of vegetable matter in the case of animal substances after oxidation.

It is thus essential that the evidence afforded by the proportion of organic carbon to nitrogen should be supplemented by an inspection of the source, and by a consideration of the mineral nitrogenous ingredients—ammonia, nitrates, and nitrites—all of which are principally derived from the decomposition of animal matters.

Albuminoid ammonia.—The ammonia yielded on distillation with alkaline permanganate is so frequently made the only measure of the organic matter present in water that a few words are necessary to indicate what is the importance to be attached to the results obtained in this simple process. According to its author, the late Mr. Wanklyn, 'deep spring water is often so pure as not to yield 0.01 part of albuminoid ammonia per million; and unless mixed

with surface water does not yield so much as 0.05 part.' 'The filtered water supplied by water companies—no matter whether derived from a lake, from clean mountain streams, or from defiled rivers—yields from 0.05 to 0.10 part of albuminoid ammonia per million; and, indeed, if the filtration be efficient, approximates to 0.05.' 'When the filters are over-taxed, as happens in the rainy season and in the winter, water companies supply imperfectly-filtered water, in which as much as from 0.10 to 0.20 part of albuminoid ammonia is found.' This statement must be accepted with great reserve, for in the winter months such surface waters almost invariably contain a much larger proportion of organic matter than during the dry season, thus accounting for the increase in albuminoid ammonia quite irrespective of any over-taxing of the filters. On the other hand, the albuminoid ammonia is the chemical ingredient in water which is most affected by filtration. It would appear, therefore, that suspended particles of vegetable and animal matter, which are removed by sand filtration, are particularly productive of ammonia on distillation with alkaline permanganate. In fact, the chemical difference between a water before and after sand filtration is often only attested by the diminished proportion of albuminoid ammonia yielded by the filtered water.

Oxygen or permanganate process.—The analytical value of measuring the proportion of organic matter in water by the amount of permanganate it is capable of decolorising is discussed in the section of this article on *Water analysis*, and it will be sufficient here to give some idea of how the results are to be interpreted. As in the case of the organic elements determined by combustion, it has here again been attempted to establish a scale of classification, which, however, must also be used with the greatest caution and in conjunction with the other analytical data, as well as with regard to the water's source and history. Thus the following artificial standards have been suggested:—

	Oxygen absorbed in three hours at room temperature from potassium permanganate by 100,000 parts of water	
	For Upland Surface Water	For other Water
Class I. Water of great organic purity . . .	0-0.1 part	0-0.05 part
" II. " medium " . . .	0.1-0.3 "	0.05-0.15 "
" III. " doubtful " . . .	0.3-0.4 "	0.15-0.3 "
" IV. Impure water . . .	above 0.4 "	above 0.2 "

It will be readily understood that a great drawback to this permanganate process consists in its not distinguishing between nitrogenous and non-nitrogenous organic matter. Hence it is very desirable that, if the combustion process cannot be resorted to, it should be supplemented by a determination of the 'albuminoid ammonia,' or of the Kjeldahl nitrogen (see p. 403).

Mineral nitrogen (ammonia, nitrates, and nitrites).—The importance of these ingredients is an indirect one. In themselves they in no way influence the wholesomeness of drinking

water; but, on the other hand, they are of consequence as indicating what the previous history of the water has been. Thus, in the ordinary process of decomposition to which organic matters are subjected in nature, the nitrogen is principally liberated in the form of ammonia, and this, by subsequent fermentative oxidation, may become converted into nitrites and nitrates. Moreover, owing to the far greater average richness in nitrogen of animal over vegetable matters, it is evident that these primary and secondary products of decomposition

furnish valuable evidence as to the previous contact of water with nitrogenous, and more especially animal, substances. As a general rule, the presence of ammonia indicates a more recent contact with such matters than does that of nitrates or nitrites, although in the case of some deep subterranean waters it appears that the nitrates originally present in the water have undergone reduction to ammonia, and hence the latter in such cases must be regarded as evidence of a more remote character even than the nitrates themselves. Again, in the ordinary course of nitrification in nature the ammonia is wholly converted into nitrate, the preliminary oxidation to nitrite being rapidly passed over; but if water containing nitrates is brought in contact with organic matter, these nitrates become more or less reduced to nitrites through the agency of certain micro-organisms (P. F. Frankland, Chem. Soc. Trans. 1888, 373; Warington, *ibid.* 742), and hence the presence of nitrites generally constitutes evidence of contamination with organic matter subsequent to the original nitrification, rather than to the latter having been imperfect. The fact must also not be lost sight of that nitrates can be reduced by certain microbes in the presence of organic matter with elimination of the nitric nitrogen in the free state, or as oxides of nitrogen, and that a contamination of the nitrified water may thus lead to the more or less complete removal of the mineral nitrogen. The absence of nitrates may thus, under some circumstances, actually indicate contact with animal matter instead of freedom from it (Munro, Chem. Soc. Trans. 1886, 632).

It must also be remembered that, in the case of surface waters, the mineral nitrogen may undergo removal through being taken up as food by plant-life, and thus the evidence of previous contact with animal matters be destroyed.

As the hygienic significance of contact with animal matters consists in the possibility of the ingress of pathogenic microbes (which may at any time be present in sewage and similar animal refuse), it is obvious that the evidence of such previous contact afforded by the presence of mineral nitrogen in any excessive proportion must be viewed as serious, if the history of the water furnishes no guarantee that any such organised poisons which may have gained access would have been subsequently removed, whilst the evidence is of far less consequence, or may indeed become entirely negligible, if in the subsequent history of the water it has undergone processes of purification which practically preclude the possibility of such poisons being still present. Until the application of bacteriology to questions of water supply, it was not possible to ascertain the efficiency of processes of water purification in this respect. But we now know that the exhaustive filtration through porous strata which spring and deep well water has undergone practically guarantees the removal of any micro-organisms which may have been originally present; in the case of river and shallow well waters, on the other hand, the chance of such removal is much less, and hence in such waters the evidence afforded by mineral nitrogen of previous contact with animal matters must be viewed with suspicion, whilst

in the spring and deep well waters it may often be disregarded altogether.

Chlorine.—This element is invariably in a state of combination—generally as sodium chloride, and hence quite innocuous. Its determination in potable water, however, is of importance as often affording information as to whether the water has been in contact with refuse animal matters or not. In this respect it is often more useful than the mineral nitrogen, as, once present in water, it cannot by any natural processes be removed. Its diagnostic value is due to the fact that human urine contains 500 parts of chlorine, or 824 parts of common salt in 100,000 parts. It is, of course, inapplicable in the vicinity of the sea and of natural salt deposits. In British waters free from animal pollution the average proportion of chlorine may be taken as 1 part per 100,000; but it is subject to very great variations.

There are, however, many other refuse liquids besides sewage which contain large quantities of chlorides, such as the effluents from dye and bleach-works, tanneries, paper-mills, alkali-works, and especially tin-plate and galvanising works, the proportion being often far in excess of anything ever found in sewage.

In America much attention has been bestowed on the proportion of chlorine present in unpolluted water at different distances from the sea-board. The points at which such waters exhibit the same amount of chlorine are joined by lines termed 'isochlors,' and these isochlors are found to be roughly parallel to the coastline. Any water submitted for examination is then remanded for further inquiries if it exhibits more chlorine than is normal for the isochlor upon which the source of the particular water is situated. This is an attempt to make the chlorine a measure of the sewage contamination past and present, in much the same way as the proportion of total combined nitrogen has been employed by others. It has the advantage over the latter, inasmuch as the chlorine is practically permanent whilst the nitrogen is removable in various ways; but, on the other hand, the chlorine is subject to great variations within a small area, according to local circumstances, more especially geological. The chlorine, moreover, only testifies to contamination by liquid, and not by solid, excrements, and in this respect also is of less general applicability than the total combined nitrogen.

Hardness.—This term is applied to those ingredients in water which react with soap and produce an insoluble 'curd,' the principal substances in question being the various salts of calcium and magnesium, which, entering into double decomposition with sodium stearate (hard soap) or potassium stearate (soft soap), give rise to calcium and magnesium stearates, both of which are insoluble bodies, and soluble salts of sodium or potassium. On this account the salts of calcium and magnesium are manifestly detrimental to the fitness of the water for washing. As regards the influence of these salts upon the quality of drinking water, opinion is divided. Some consider the presence of a certain proportion of these salts desirable as furnishing the materials necessary for bone-formation; others contend that if present in more than a moderate proportion, they tend to

these calcareous concretions in the system, whilst, lastly, others regard their presence or absence as immaterial from a hygienic point of view. Further, by some authorities the sulphates and chlorides of calcium and magnesium (the so-called 'permanent hardness') are regarded as more objectionable than the bicarbonates or 'temporary hardness.' Again, there are many who view the presence of the salts of magnesium with more suspicion than those of calcium, and, indeed, magnesium waters are very generally credited with the power of causing phosphatic calculi, goitre, and cretinism. On this account it has sometimes happened that waters which were otherwise of most unimpeachable quality have been discarded in consequence of their containing a few parts per 100,000 of magnesia. All these views concerning the influence of calcium and magnesium salts are, however, based upon very unsatisfactory evidence. The Rivers Pollution Commissioners, in prosecuting their inquiry into this subject, found that 'where the chief sanitary conditions prevail with tolerable uniformity, the rate of mortality is practically uninfluenced by the softness or hardness of the water supplied to the different towns, and the average rate of mortality in the different water divisions varies far less than the actual mortality in the different towns of the same division. They were of opinion that, whilst waters of excessive hardness may be productive of calculus and perhaps other diseases, soft and hard water, if equally free from deleterious organic substances, are equally wholesome.' The question of magnesia in drinking water has been discussed by the writer ('What is the Importance of Magnesia in Drinking Water,' P. F. Frankland, Transactions of the Internat. Congress of Hygiene and Demogr. London, 1891), from whose inquiry it appears that whilst the amount of magnesia in the water supplied to most large towns is very small—generally not more than 1-2 parts of MgO per 100,000—it is much larger than is generally supposed in the well-water consumed by such a large portion of the population. Thus in the case of fifty brewery waters from all parts of the kingdom, the average amount of magnesia (MgO) was 3.41 parts per 100,000. It must also be remembered that the geological formation richest in magnesia (the magnesian limestone) is only very slightly represented in this country, so that the proportions of magnesia met with in the dolomitic districts of the Continent must be much larger.

Until, therefore, a far more searching inquiry than hitherto has been made into the alleged effect of such waters upon health, it would appear undesirable that any importance should be attributed to such proportions of magnesia as the above in drinking waters which are otherwise of unimpeachable purity.

The effect of Clark's process on magnesian waters is noteworthy. As a general rule, the proportion of magnesia removed by the treatment with lime is small—much smaller than that of the lime removed; but it is particularly worthy of notice that in cases where caustic soda was used in conjunction with lime, as is so frequently done in the softening of water for industrial purposes, the magnesia may be removed in a greater proportion than the lime,

and as a matter of fact magnesium hydroxide is less soluble even than calcium carbonate.

The hardness of water not unfrequently throws light upon its previous history, for the food of both man and animals is of necessity rich in lime, and nearly the whole of this is in adult life again found in the liquid and solid excreta; hence water obtained from soil which has been much polluted with animal matters always exhibits a large amount of permanent hardness.

PURIFICATION OF DRINKING WATER.

Inasmuch as the impurities are either suspended or dissolved, mineral or organic, and the organic either animate or inanimate, it follows that the subject of purification may be considered from different points of view, according to the particular class of impurities the removal of which is under discussion. Until recently all the more important processes of drinking water purification were filtration processes, those depending upon precipitation being more especially of importance in connection with water for industrial purposes (see p. 391). Now, however, methods of more or less sterilising water by means of hypochlorites, ozone, or ultra-violet light are sometimes being resorted to (see p. 417).

Purification of drinking water on large scale.—

All surface water is liable to turbidity, and in times of rain and flood the amount of suspended matter may become excessive. It is, therefore, desirable that all surface water, even that from upland sources, should be submitted to purification before distribution for domestic purposes. The purification of surface water is best initiated by permitting the water to remain at rest in storage reservoirs for some days or even weeks, the greater part of the suspended matter thus becoming precipitated, and some destruction even of the dissolved organic matter also taking place. During storage most important biological changes also take place (see later). The process of filtration resorted to on the large scale is almost invariably that through sand of different degrees of coarseness. This method was inaugurated by Simpson, the engineer to the Chelsea Company in 1829, and has since been adopted in an ever-increasing number of places all over the world. The filter beds, as usually constructed, are 10-16 ft. in depth, often upwards of an acre in area, made water-tight with masonry, concrete, or puddled-clay walls. On the bottom are collecting drains, upon which is placed a layer of broken stone about 6 ins. in thickness, following upon which are layers of coarse gravel, fine gravel, and uppermost a stratum of fine sand, 1-4 ft. in thickness. The water is kept at a depth of 1-4 ft. above the surface of the fine sand, the rate of filtration varying in different works. For construction and cost of filtration plant, see Donnan and Chisholm, *Modern Methods of Water Purification*, London, 1911, 125. The greater part of the suspended impurities is retained in the downward passage of the water by the first few inches of fine sand, and sooner or later, sometimes in the course of a few weeks, causes the clogging of the filter. When the rate of filtration is too much retarded for practical purposes, the filter

surface of the sand is removed, after which the filtration can be continued until the filter is again choked, when the surface is again scraped off, the process being repeated until the stratum of sand becomes too thin to be efficient, after which the original thickness of the sand-layer is restored by means of washed sand. The sand scraped off is generally thoroughly washed, allowed to dry, and then used again. The particulars for the several sections of the Metropolitan supply, shown below, will serve to illustrate the method of working.

Besides the filter beds just described, some of the works drawing from the Thames are now using an auxiliary process of filtration through the natural gravel beds which form the banks of the Thames at Hampton. These gravel beds are at all times full of water, which forms, as it were, an underground river, and underground pipes are laid in this gravel and connected with a pumping well in order to utilise this water, which is always clear and bright in consequence of the natural filtration which it has undergone. In order to increase the supply of this underground water the gravel bed is flooded with water directly from the Thames, for which purpose a second series of perforated pipes are laid parallel to the first and placed at a distance of about 30 yards from them. This second series of pipes is placed in direct communication with the Thames, but at the point of ingress is

placed a small vertical sand filter to arrest the coarser impurities.

Such sand filters, although very efficient in removing the suspended matter, have comparatively little action upon that which is dissolved. Thus the following figures exhibit the composition of the York water supply, before and after filtration through sand:—

(Results of Analysis expressed in parts per 100,000.)

	Before filtration	After filtration
Total solid matters	28.40	26.20
Organic carbon	0.123	0.119
Organic nitrogen	0.023	0.022
Ammonia	0	0
Nitrogen as nitrates and nitrites	0.077	0.089
Chlorine	1.6	1.6
Temporary hardness	11.5	10.9
Permanent hardness	7.1	7.1
Total hardness	18.6	18.0
Micro-organisms (colonies yielded by 1 c.c. of water on cultivation with gela- tin-peptone)	31,200	122

It was formerly supposed that such sand filtration could have little or no effect in removing the micro-organisms present in water, as the interstitial spaces between the grains of sand are so large in comparison with the minute dimensions of the microbes. It was first shown

METROPOLITAN WATER SUPPLY, JANUARY, 1911.

Monthly Reports by Metropolitan Water Examiner to Local Government Board.

by Koch in Germany, and by the writer in this country, that nearly all the microbes in water may be removed by the sand-filters (Koch, Bericht der Deputat. f. die Verwaltung der Canalisationwerke, Berlin, 1883; P. F. Frankland, Proc. Roy. Soc. 1885; Proc. Inst. Civ. Engineers, 1885-6; J. Soc. Chem. Ind. 1885, 1887), and this result has been since confirmed by many other investigators.

It was, in fact, supposed by Koch and his pupils that the sand filtration really removed all the microbes originally present in the water, and that those always found in the filtered water had gained access subsequent to filtration. The writer had, however, from the first shown that in the case of the monthly examinations of the

London water supply there was an obvious relationship between the numbers of microbes in the unfiltered and filtered waters respectively, necessitating the conclusion, therefore, that the sand filters can only be credited with removing a portion and not the whole of the micro-organisms present. This is sufficiently conspicuous from the tables on next page, which record some of the writer's results obtained with the London water supply during the year 1886, and reported to the Local Government Board (P. F. Frankland, J. Soc. Chem. Ind. 1886). The unfiltered Thames water was in every case collected near the intakes of the several water companies at Hampton, and the filtered water from the mains of the Chelsea, West Middlesex, Southwark,

Grand Junction, and Lambeth Companies respectively.

C. Fraenkel and Piefke (Zeitsch. Hygiene, 8, 1890, 1-40) subsequently demonstrated by direct experiment that particular species of bacteria purposely introduced into the unfiltered, were still present, although in greatly diminished numbers, in the filtered water.

The wonderful efficiency of these sand filters in removing microbes was at first very difficult to account for, but it is now recognised to depend upon the impervious nature of the slimy deposit which forms upon the surface of the sand, and until such a coating has been established the filter has but little effect in removing micro-organisms (Piefke, Aphorismen über Wasser-versorgung, Zeitsch. Hygiene, 7, 1889, 115-179). This slimy deposit consists not only of silt, mud, and colloidal matter, but also of a multitude of living forms—diatoms, green and blue algae, innumerable bacteria, fungi, and protozoa. Many of these forms actually feed on

bacteria. The rate at which filtration is carried on is also a most important factor, the more rapid the rate the less efficient being the purification (P. F. Frankland, Proc. Inst. Civ. Engineers, 1885-6). Although the removal of bacteria is not attributable to the sand particles as such, there is abundant evidence that the finer the sand and the greater its depth the more efficient is the filtration. This is doubtless due to a better support being given to the filtering skin, and to the finer and thicker layer of sand regulating the passage of water through the medium, whilst the water is also brought into more intimate and prolonged contact with the colloidal matter with which the sand of a matured filter is clothed. The statistics of the London water-works show that the cost of filtration as carried out by them averages about 0.1d. per 1000 gallons.

In countries liable to extreme cold—indeed, even in cold winters in this country—the process of sand filtration offers great difficulties, in consequence of the freezing of the filters; and this

has, in Berlin, been guarded against by the construction of a number of covered filter-beds. In the United States, where the same difficulty exists, the Hyatt system of filtration has been employed on a considerable scale. In this the water is first treated with a minute quantity of alum (about $\frac{1}{2}$ grain per gallon), after which it passes through a steel filtering chamber, consisting of a vertical cylinder the diameter of which is nearly twice its height. This cylinder is divided by a horizontal diaphragm, capable of withstanding the hydrostatic pressure necessary for rapid filtration. The lower half contains the filtering material, composed of 2 parts coke and 3 parts sand. The upper part of the cylinder is used for washing the filtering material, which at regular intervals is transferred into it in a state of violent agitation by hydraulic currents, the impurities flowing away through pipes situated near the top of the cylinder. In the process of filtration the water is admitted through pipes to the upper part of the lower section of the cylinder, and it is drawn off through perforated cups, which permit the water, but not the sand, to pass. It is claimed that the efficiency of the system depends more upon the successful precipitation and entanglement of germ life by the coagulant alumina than upon any special merits of the filter (Potable Water, Floyd Davis, Iowa, U.S. 1891). The cost of maintenance is said to be only one-fifth of that entailed by filter beds.

In recent years the use of mechanical filters has been gaining ground in Great Britain also, the Jewell, Bell, and Candy filters being those most commonly employed (see Modern Methods of Water Purification, Don and Chisholm, London, 1911; see also *Bacteriology of water*, below). The Pusch-Chabal system consists in submitting the water to successive processes of filtration, sometimes as many as six stages, beginning with coarser grades of gravel and ending with fine sand, being employed. It is specially suitable for very turbid waters, as the life of the fine sand filter is greatly prolonged. It has been used at Magdeburg and other places (see Don and Chisholm, l.c.).

Of other methods of drinking-water purification on the large scale the only one that need be mentioned is Anderson's. The method consists in passing the water slowly through revolving iron cylinders about two-thirds filled with iron borings. A small quantity of the iron continuously passes into solution, so that the water becomes impregnated with ferrous iron, which subsequently, when the water flows into a settling tank, is converted into the ferric state with precipitation, a large proportion of the organic matter in solution being removed in the process, whilst a very considerable diminution in the number of vital germs is also effected. After undergoing oxidation in the settling tank, the water is finally filtered through sand before distribution. It takes $3\frac{1}{2}$ mins. for the water to pass through the rotating cylinder, the entire process occupying about 6 hours (Anderson, Proc. Inst. Civ. Engineers; Engineering, 39, 525). This process has been used on a large scale at Antwerp and Paris.

Purification of drinking water on the small scale.—The filtration of water on the small scale was already known to the ancients. Thus Pliny mentions a process by which water was clarified by

passage through wool. An immense number of different materials have been employed during recent years, but space will only permit of the brief consideration of a few of the more important ones.

Animal charcoal is employed in a number of common household filters, and from the invaluable services which it yields in sugar-refining it was anticipated that it would be highly efficient as a water filter. Unlike sand, it not only acts upon the suspended matters, but also removes a considerable proportion of the dissolved organic matter, and even some of the temporary hardness. Unfortunately, however, its action is very transient, and it generally soon becomes the seat of numerous organic growths, which are favoured by the calcium phosphate it contains, and the filtered water is then often rendered more impure than the unfiltered.

Vegetable charcoal has but little effect on the dissolved organic matters, although if in a sufficiently fine state of division it is an excellent strainer for suspended impurities (see table below).

Bischof's spongy iron, obtained either by reduction of hematite or of roasted pyrites, has a remarkable power of removing dissolved organic matters, as well as temporary hardness and nitrates, and this power is far more permanent than that of animal charcoal. It was for some time also employed on the large scale, in conjunction with sand, at the Antwerp Waterworks. The effect of filtration through animal charcoal and spongy iron respectively is exhibited in the table below.

Since the recent great advances in bacteriological science, it has become evident that the removal of micro-organisms from drinking water is a matter of much greater importance than the removal of organic matter, and hence it is in respect of this property that the value of filters is now generally estimated. The writer has shown (The Removal of Micro-Organisms from Water, P. F. Frankland, Proc. Roy. Soc. 1885) that several substances—such as coke, wood-charcoal, spongy iron, &c.—in a sufficiently fine state of division are capable of entirely removing all microbes in water passed through a stratum of a few inches of these materials. This power, which is quite independent of any chemical action (thus in the case of coke and wood-charcoal there is little or no removal of dissolved organic matter), is, however, not maintained unless the materials are frequently renewed; and in the case of animal charcoal which has been in use for a short time (one month) the number of microbes was found to be far greater in the filtered than in the unfiltered water. The most conspicuous instance of biological, as opposed to chemical, filtration is furnished by Chamberland's unglazed porcelain filter, which entirely removes microbes, but has no chemical action whatever (see table on next page).

A number of household filters in actual use have been examined with regard to their power of removing microbes by Plagge (Public Health Section of Germ. Assoc. of Naturalists and Physicians, 1886), who divides them into six classes, according to the materials used: (1) carbon filters, (2) stone and sand filters, (3) spongy-iron filters, (4) paper filters, of various kinds, (5) porous earthenware filters (Chamberland), (6) asbestos filters (Breyer, Hesse, 1886).

and Schirmer). The carbon filters were found not only to admit of the free transmission of microbes, but in some cases the numbers in the filtrate greatly exceeded those in the unfiltered water. Thus in one case 68 colonies were obtained from 1 c.c. of the unfiltered, and 12,000 from 1 c.c. of the filtered water. The stone and sand filters were all found to be worthless. The spongy-iron filter yielded the following results: unfiltered water, 38,000 colonies from 1 c.c.; filtered, 18,000-24,000 colonies from 1 c.c. The paper filters all yielded very unsatisfactory results; the earthenware and asbestos filters, on the other hand, gave in nearly every instance a filtrate practically free from microbes. (For par-

ticulars concerning the sterilising power of the Chamberland filter, see also Miquel, *Analyse Bactériologique des Eaux*, Paris, 1891.) The principal drawback to these porous earthenware filters is the rapid diminution in the rate of filtration which they exhibit. More satisfactory in this respect are the Berkefeld filters, similarly constructed of burnt infusorial earth (Nardt-meyer, *Zeitsch. Hygiene*, 1891, 10, 145; Bitter, *ibid.* 155). Neither the Chamberland nor Berkefeld filters permanently yield sterile water, some of the bacteria in the unfiltered water sooner or later growing through the pores. It is, however, doubtful whether any of the ordinary pathogenic bacteria would do this, as none of them are

(Results of Analysis expressed in parts per 100,000.)

³ P. F. Frankland, *Proc. Roy. Soc.*, 1885, 300.

known actually to multiply extensively in ordinary drinking water (Kühler, *Zeitsch. Hygiene*, 1890, 10, 48).

W. E. Hall has described a simple apparatus for the extraction of micro-organisms from samples of water. The sample is collected in a small straining jar through which any quantity of water can be passed, and the organisms retained in a quantity of water convenient for carriage.

From this concentrated sample the organisms can be extracted by passing it through a filter paper about 1½ in. diameter placed over a small funnel attached to a vessel from which the air is extracted by means of an exhaustor consisting of a modified form of filter pump.

The organisms are finally washed off the filter paper by means of a wash bottle with about 2 c.c. of water in which the organisms can readily be examined in a stage trough or placed in small quantities on a compressor slide (*J. Soc. Chem. Ind.* 1924, 43, 290).

Purification of drinking water by distillation.—This is, of course, the most effectual mode of freeing water from all its impurities. It is

resorted to, on a considerable scale, at sea, both for steam and sailing vessels. (For description of forms of apparatus in actual use v. Fischer, *Technologie d. Wassers*, Brunswick, 1880, 201-208.) The insipid taste of the distilled water can be removed either by aëration, or by filtration through animal charcoal or other porous substances. Distilled water is also employed to some extent for the manufacture of aerated waters and for artificial ice.

Purification of drinking water by boiling.—The purification consists, of course, only in the destruction of living organisms present in the water, but this is from an hygienic point of view of the greatest importance. In its action it is far more reliable than any process of filtration, and should be invariably resorted to in the case of waters which bear any suspicion of sewage contamination. The rapid taste of the boiled water may be removed by passage through a filter, which, however, should be exclusively employed for this purpose and not for filtering unboiled water. A convenient form of apparatus for sterilising large quantities of water—e.g. for hospitals, barracks, &c.—is described by

Miquel (*Manuel d'Analyse bactériologique des Eaux*, Paris, 1891, 198). The more extensive use of boiled instead of filtered water is one of the chief sanitary desiderata of the day. Although absolute sterility cannot be guaranteed by a few minutes' ebullition, yet the reduction in the number of microbes by this simple process is so great that it may be safely regarded as ample for practical purposes. Thus Miquel and Wada (*ibid.* 185) found in the case of the Ourcq-canal water of Paris:—

WATER FOR INDUSTRIAL PURPOSES.

Of the numerous industrial uses to which water is put, the most general and important is the raising of steam. The composition of the water supplied to steam-boilers is a matter of great consequence, as the use of unsuitable water may cause the corrosion of boiler-plates and the formation of deposits, which not only occasion a serious loss of heat but may also lead to most disastrous explosions (*v.* **BOILER INCORUSTATIONS AND DEPOSITS**).

Water for other industrial purposes.—(1) For brewing, see art. **BREWING**. For use in bakeries, the water should be in all respects of the same degree of purity as is demanded for drinking purposes.

(2) For the textile industries the character of the water employed is often of great consequence. Thus in bleaching and dyeing the presence of iron and manganese, even in very small quantities, is highly deleterious, giving rise to iron and manganese stains on the bleached goods, and causing spots and modifications in the shades of dyed materials. Hard water, again, involves the use of larger quantities of alkali and soap in the several operations of boiling, scouring, and milling, and the insoluble lime-soap is left adhering to the fibre, often preventing the subsequent application of mordant or dye. In those operations, again, in which dyed fabrics are soaped, the lime-soap often injures the brilliancy of the colour, whilst in other cases the earthy soaps precipitated on the fibre act as mordants, and attract the colouring matters on those parts of the goods where it is not wished to fix them. In general, hard water has the effect of dulling many colours, and if due to bicarbonates retards, or even prevents, the dyeing of such colours as require an acid bath (*e.g.* cochineal scarlet). In some cases hard water containing bicarbonates wastes the mordants by precipitation in the bath instead of on the fibre, whilst it is sometimes actually beneficial for the washing of goods which have been mordanted with basic mordants. Such water is unsuitable for the solution of many coal-tar colours—*e.g.* methyl violet—a portion of the latter being lost as a tarry precipitate, whilst the goods are often spotted. For dyeing with some colours—*e.g.* alizarin and logwood—the

presence of a certain amount of lime is almost indispensable; a pure water to which a known quantity of lime-salt has been added is, however, preferable to a naturally hard water, especially if the latter is of variable composition. Water containing alkaline carbonates is sometimes advantageous, *e.g.* in wool-scouring, and in those dyeing operations in which the addition of sodium carbonate is prescribed; but in mordanting, in the dyeing with many colours, and in the washing of dyed goods, it is often very prejudicial; in these cases it should be neutralised with sulphuric or acetic acid. Acid waters are generally highly injurious, and should be neutralised with sodium carbonate. Sulphuretted hydrogen in water is also very objectionable in many operations of dyeing, more especially in mordanting with metallic salts (*Hummel, Dyeing of Textile Fabrics*). For the manufacture of paper, water containing iron is highly objectionable, giving rise to stains, whilst the presence of hardness is objectionable in causing the decomposition of the rosin-soap.

(3) For tanning, pure water is also a desideratum. Water much contaminated with organic matter causes injury to the surface of the leather, and sometimes a corrosion from the flesh-side of the skin. Water containing carbonic acid, or the bicarbonates, or calcium and magnesium sulphates, causes the hides to swell, whilst the chlorides prevent the swelling, and hence sea-water cannot be employed for the purpose. Hard water occasions a less perfect utilisation of the tanning materials, and an excess of chlorides retards the tanning process and causes the leather to attract moisture; the presence of iron is not so objectionable as is commonly supposed (*Fischer, Das Wasser*, 49–51).

(4) In sugar-refining the sulphates and alkaline carbonates are more productive of molasses than the chlorides, whilst nitrates are specially objectionable, as they prevent the crystallisation of six times their weight of sugar (*Fischer, Technologie d. Wassers*, p. 286).

Purification of water for industrial purposes.

As already pointed out, some substances, although unobjectionable in drinking water, operate prejudicially when the water is employed for many industrial purposes, and numerous methods have been devised for removing these impurities or for counteracting their effects. But few methods of purification have found favour in actual practice, and to these alone will any attention be given here. The processes which have for their object the removal of matters in suspension and organic substances have been already described under *Purification of drinking water* (*v.* p. 396), whilst the processes intended for the improvement of industrial water supplies are chiefly directed to the removal of lime and magnesia salts in solution, which, as has been shown above, interferes with the success of so many industrial operations. This removal of lime and magnesia salts is frequently spoken of as 'water-softening,' in consequence of the water after such treatment requiring less soap when used for washing purposes.

Purification with lime (Clark's process).—This method of purification was first proposed by Clark, of Aberdeen, in 1841, and consists in the decomposition of calcium bicarbonate or 'temporary hardness' of water by the addition of a suitable quantity of slaked lime, according to the equation

Thus both the lime in solution as bicarbonate as well as that added in the form of hydroxide are precipitated as normal carbonate, which is almost insoluble in water. The calcium hydroxide is sometimes added in the form of milk of lime, sometimes in that of clear lime-water, but the latter is far preferable, as the quantity added can be more easily controlled and an excess avoided. The necessary quantity of calcium hydroxide is most easily ascertained by adding such an amount that, after thorough mixing, a small quantity of the water taken out yields a yellow or brown colour with a solution of silver nitrate, more water is then added, until, on similarly testing, no coloration with the silver nitrate is obtained. This test should invariably be resorted to even in the case of such waters as are of very constant composition, and which, therefore, admit of the lime being proportioned by experience, as otherwise an excess or deficiency of lime is nearly sure to result. In its original form the Clark process is carried out in large tanks in which the water can remain at perfect rest for about 16 hours, although by the use of a floating exit-pipe the clear surface water can often be drawn off after 2 or 3 hours, and before the whole of the precipitate has reached the bottom. This method has been most successfully employed on a large scale at the Colne Valley Waterworks, near Bushey, at Canterbury, Caterham, and many other places on a small scale. The 'temporary hardness' only is, of course, removed, and even this not completely, as under the most favourable circumstances a small proportion of calcium carbonate remains in solution, whilst in the case of waters containing magnesium bicarbonate the removal of the latter is generally far less complete. In addition to these bicarbonates, the salts of iron and much organic matter are also removed.

In order to obviate the large amount of storage capacity required for Clark's process, several modifications have been introduced, in which the precipitate formed by the treatment with lime is either removed by filtration or made to subside rapidly by artificial means. The most notable of these improved processes are the so-called 'Porter-Clark,' in which the precipitate is removed with a filter-press, and Gaillot and Huet's process, in which subsidence is promoted by causing the water to take a circuitous zig-zag and upward path after the addition of the lime. In this latter process both lime and caustic soda are frequently employed in conjunction as the softening agents; in this manner both 'temporary' and 'permanent' hardness can be, to a great extent, removed, thus:—

Space does not permit the description of a number of other water-softening apparatuses

which are now on the market, and which only differ from each other in the special mechanical devices for supplying the chemicals (milk of lime, lime water, sodium carbonate, or caustic soda, as the case may be) and for removing the deposit. The Archbutt-Deeley process, however, possesses certain features of interest. In this the clarification of the treated water is accelerated by stirring it up with the sludge of calcium carbonate obtained in previous precipitations, this being effected by blowing in compressed air through perforated pipes. The subsequent sedimentation takes place very rapidly, and the clear water is drawn off from the surface by means of a floating arm. Further, the danger of subsequent deposition of calcium carbonate in the service pipes, which often occurs when an insufficient time is allowed for sedimentation, is avoided by injecting carbon dioxide (obtained from a coke-stove, the gas being scrubbed with limestone to remove sulphur compounds) into the clarified water as it is drawn from the settling tank.

Magnesia has also been employed to a limited extent for softening instead of lime. Under these circumstances the following reactions may take place, especially if heat is applied:—

(Fischer, Chem. Technol. d. Wassers, Brunswick, 1880, 264).

The formation of magnesium chloride is obviously disadvantageous for boiler purposes.

A number of other processes of chemical purification have from time to time been suggested, but none of them have met with any great success. Thus attempts have been made to utilise the following reactions:

In the *Permutite* process, devised by Dr. Gans of Berlin, the water is softened by filtration through artificial zeolite (a hydrated silicate of alumina and soda) to which the name of *Permutite* has been given. The latter is made by fusing together silica or quartz, alumina or china-clay, and sodium carbonate. The fused mass is extracted with water, a crystalline body ($\text{SiO}_2=46$, $\text{Al}_2\text{O}_3=22$, $\text{Na}_2\text{O}=13.6$, $\text{H}_2\text{O}=18.4$ p.c.) being obtained. When waters containing calcium or magnesium salts are filtered through this material, the following reactions take place:—

It is claimed for this process that the whole of the hardness is removed and that the calcium or magnesium zeolite formed can be regenerated into the original permutite or sodium zeolite by treatment with a strong solution of common salt. Gans uses a manganese-permutite (zeolite,

alkalinity, and a higher oxide of manganese) for the removal of iron and manganese in water. This material can be regenerated by treatment with a solution of potassium or calcium permanganate. The manganese-permutite can also be employed for the sterilisation of water; the water is treated with permanganate in sufficient concentration to destroy bacteria, and, on subsequent filtration through manganese-permutite, the whole of the manganese is said to be retained by the filter. Calcium-permutite has been used for removing potash from molasses, lime passing into solution; the lime may be replaced by soda by passing through sodium-permutite. The plant and materials for the Permutite process can be obtained from 'Water Softeners, Ltd.,' Kingsway, London, W.C.

For the effect of softening processes on the bacteria in water, v. p. 417.

The action of water on lead, zinc, copper, and aluminium.—The action of water on these metals, and especially on lead, is of great importance in connection with the distribution and storage of water. The Romans employed leaden pipes, and Vitruvius and Galen were aware that some waters were thereby rendered deleterious. On the other hand, certain waters have so little action on lead that pipes of this material have been in use for upwards of 200 years without showing any trace of corrosion (Fischer, *Technologie d. Wassers*, 317). As a general rule, hard waters, and more especially those containing bicarbonates, do not act on lead; the greater number of active waters are soft, and generally entirely destitute of bicarbonates. The activity has been ascribed by different authorities to the presence or absence of a great variety of ingredients in the water—e.g. the presence of dissolved air (Yorke), ammonium nitrite (Medlock), ammonium carbonate (Böttcher). Some have contended that organic matters diminish the activity (Horsford), others that they increase it (Hofmann, Graham, Miller, and Noad). The latter authorities were of opinion also that the presence of dissolved oxygen and the absence of more than 3 vols. of carbon dioxide in 100 vols. of water are amongst the conditions necessary for the attack upon lead. It has also been contended that a minute proportion of calcium phosphate prevents a soft water from attacking lead (Riv. Pollut. Commis. 6th Rep. 224), whilst according to others, again, the protecting ingredient is silica (Crookes, Odling, and Tidy, Report on the Action of Water on Lead, London, 1886). In many cases the activity of the water is due to the presence of organic acids (Allen), this being doubtless a fruitful cause of moorland waters acting on lead. The activity of many waters is confined to new untarnished lead, whilst others continue to act, sometimes with increased vigour, on the old and tarnished metal (P. F. Frankland, *The Action of Water on Lead*, J. Soc. Chem. Ind. 1889, 241).

Numerous expedients have been resorted to in order to destroy this activity of some soft waters. When acidity is the presumable cause the most obvious remedy is the filtration of the water through finely-divided limestone; in practice, however, this is found to be only of temporary service, as the surfaces of the limestone become coated with a film which prevents their

being further acted on by the water. It has been found more effective to mix the water continuously with a milk of finely-divided calcium carbonate, and allowing this to subside before the water is distributed.

It is now generally admitted that the action of water on lead is of two different kinds. Of these the most obvious is that due to the acidity¹ of some waters; such acidity may be due to organic or even mineral acids, and can be determined by titration with appropriate indicators. Such acid waters have, in general, a continuous action on lead. The acidity can, of course, be neutralised by the addition of lime, finely-divided calcium carbonate, or most effectively by sodium carbonate. It was, however, shown many years ago by the writer that such neutralisation does not necessarily entirely stop the action of the water on lead, and that this is often only secured by adding a considerable excess of sodium carbonate. Similarly there are many natural waters, which, although slightly alkaline with small proportions of calcium bicarbonate, nevertheless act on lead. Such action of neutral or even slightly alkaline waters is now usually termed '*erosive*' as distinguished from the '*plumbosolvent*' action of acid waters. These remarkable phenomena have only received a satisfactory explanation since the recent advances in physical chemistry have illuminated the subject of chemical equilibrium.

This matter is very ably dealt with in an important paper by Paul, Ohlmüller, Heise, and Auerbach (*Arbeiten a. d. kais. Gesundheitsamte*, 1906, 23; *Untersuchung über die Beschaffenheit des zur Versorgung der Haupt- und Residenzstadt Dessau benutzten Wassers, insbesondere über dessen Bleilösungsfähigkeit*). The conclusions arrived at by these authors are:—

1. *Dissolved oxygen* is necessary for the solution of metallic lead in pure water. Experiments made with distilled water, which had been saturated with air freed from carbon dioxide, showed that nearly the whole of the oxygen (amounting to about 9 mgms. per 1 litre) was taken up presumably according to the equation:

The water, which was at 18°, took up about 115 mgms. of lead per 1 litre. By increasing the proportion of oxygen in the air used for saturating the water the amount of lead taken up was at first also increased (up to about 140 mgms. Pb per 1 litre), but this was followed by a sudden drop to an amount which remained practically constant (about 108 mgms. per 1 litre for about 14.5 mgms. O₂ dissolved in 1 litre water). This sudden drop is referred to the appearance of a precipitate (*solid phase*) preventing further supersaturation of the water with lead hydroxide. (The authors did not determine the exact composition of the solid phase, which may have been Pb(OH)₂, or more probably one of its anhydrides.)

2. *Free carbonic acid* diminishes the plumbosolvent effect of the simultaneously present dissolved oxygen. Thus, in an experiment with distilled water made to contain about 8 mgms. O₂ and 40 mgms. CO₂ in 1 litre, the amount of lead

¹ See a very important paper on 'The Acidity and Alkalinity of Natural Waters,' by James Walker and A. A. Kay (*J. Soc. Chem. Ind.*, 1912, 31, 1473).

taken up was about 11 mgms. per 1 litre, or about $\frac{1}{2}$ of that dissolved when the same proportion of dissolved oxygen was present in the absence of carbonic acid. This diminished plumbosolvency is, of course, attributable to the formation of a more insoluble solid phase, viz. either PbCO_3 , or more probably some basic carbonate such as $2\text{PbCO}_3 \cdot \text{Pb}(\text{OH})_2$.

3. Sodium bicarbonate in the absence of any appreciable quantity of free carbonic acid greatly reduces the plumbosolvency of water; thus in similar experiments, in which the same proportion (about 9 mgms. O_2 per 1 litre) of dissolved oxygen was retained, but along with 35 mgms. of NaHCO_3 per litre, the amount of lead taken up was only 0.6 mgm. per litre of water. This, again, is attributable to the diminished solubility of the solid phase in the solution of the sodium bicarbonate. The amount of lead taken up by the water is limited by the *solubility product*; thus a saturated solution of lead carbonate will contain a small concentration of PbCO_3 molecules, together with $\text{Pb}^{++}\text{CO}_3^{--}$ ions, of which only the PbCO_3 molecules are in direct equilibrium with the solid phase (precipitated lead carbonate). The concentration of the PbCO_3 molecules will always remain constant as long as there is any of the solid phase present, but this concentration is very small. The concentration of the ions, on the other hand, is determined by the dissociation equilibrium. Thus, representing the molecular concentrations of the respective bodies by the formulæ enclosed in brackets, we have—

$$[\text{Pb}^{++}] \times [\text{CO}_3^{--}] = k \times [\text{PbCO}_3]$$

in which k is a constant. But in saturated solutions, as already seen above, $[\text{PbCO}_3]$ is constant, therefore $k \times [\text{PbCO}_3]$ is also constant, and can be represented by S , which is termed the *solubility product*, thus—

$$[\text{Pb}^{++}] \times [\text{CO}_3^{--}] = S$$

$$\therefore [\text{Pb}^{++}] = \frac{S}{[\text{CO}_3^{--}]}$$

which obviously signifies that the concentration of the Pb^{++} ions will be the smaller the greater the concentration of the CO_3^{--} ions. (If the solid phase is a basic carbonate, then it can be shown that the concentration of the Pb^{++} ions must be inversely proportional to the concentrations of the CO_3^{--} and the OH^- ions.)

In solutions of free carbonic acid the concentration of CO_3^{--} ions is very small (because carbonic acid being a very weak acid is only very slightly dissociated into ions), whilst in solutions of NaHCO_3 the concentration of CO_3^{--} ions is much greater, and, therefore, the concentration of the Pb^{++} ions will be correspondingly diminished, or, in other words, a much smaller proportion of lead will pass into solution. (It should be mentioned that the phenomena may be complicated by the circumstances that the nature of the solid phase may be different according as the metallic lead is placed in contact with a solution of free carbonic acid or bicarbonate respectively.)

4. The simultaneous presence of free carbonic acid and sodium bicarbonate leads to the following considerations:—

further $\text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$, whilst to a much less degree $\text{HCO}_3^- \rightleftharpoons \text{H}^+ + \text{CO}_3^{--}$. These dissociations are expressed by the equations

$$(1) [\text{H}^+] \times [\text{HCO}_3^-] = k_1 \times [\text{H}_2\text{CO}_3]$$

$$(2) [\text{H}^+] \times [\text{CO}_3^{--}] = k_2 \times [\text{HCO}_3^-]$$

in which the values

$$k_1 = 3.04 \times 10^{-7}$$

$$k_2 = 1.3 \times 10^{-11}$$

are known (J. Walker and W. Cormack, Chem. Soc. Trans. 1900, 77, 5; Bodländer, Zeitsch. physikal. Chem. 1900, 35, 23).

From equation (2)

$$[\text{CO}_3^{--}] = k_2 \times \frac{[\text{HCO}_3^-]}{[\text{H}^+]}$$

and combining this with equation (1) we have

$$[\text{CO}_3^{--}] = \frac{k_2}{k_1} \times \frac{[\text{HCO}_3^-]^2}{[\text{H}_2\text{CO}_3]}$$

but with PbCO_3 as solid phase we had

$$[\text{Pb}^{++}] = \frac{S}{[\text{CO}_3^{--}]}$$

which can, therefore, be written

$$\text{Pb}^{++} = \frac{S \times k_1}{k_2} \times \frac{[\text{H}_2\text{CO}_3]}{[\text{HCO}_3^-]^2}$$

But, inasmuch as free carbonic acid is very little, and sodium bicarbonate very much dissociated, the value of $[\text{H}_2\text{CO}_3]$ may be taken as proportional to the molecular concentration of the free carbonic acid, and $[\text{HCO}_3^-]$ to that of the sodium bicarbonate, and thus the concentration of the Pb^{++} ions will be directly proportional to that of the free carbonic acid, and inversely proportional to the square of that of the sodium bicarbonate.

This important theoretical deduction was experimentally verified by placing lead in contact with water containing 8.3 mgms. O_2 , 35.3 mgms. NaHCO_3 , and about 33 mgms. CO_2 per 1 litre, with the result that the amount of lead in solution was found to be about 1 mgm. per 1 litre, and thus slightly but distinctly greater than in the previous experiment in which there was no free carbonic acid present, and in which 0.6 mgm. Pb per 1 litre was taken up by the water.

In ordinary natural waters the phenomena are complicated by the simultaneous presence of other salts, especially chlorides and sulphates. Both PbCl_2 and PbSO_4 are considerably more soluble than the carbonate. On adding 71 mgms. Na_2SO_4 per 1 litre to the last artificial water mentioned above, it was found that the proportion of lead taken up was about tripled, being about 3 mgms. per litre. This increase must, of course, depend on the presence of PbSO_4 molecules in solution, and not on an increase in the concentration of the Pb^{++} ions, which it was shown was already fixed by the concentrations of the carbonic acid and bicarbonate. Now by removing some of the free carbonic acid (e.g. by adding Na_2CO_3) the concentration of the Pb^{++} ions will be diminished, and this will have the effect of also diminishing the amount of lead in solution due to the solubility of the PbSO_4 , for the amount of undissociated PbSO_4 is dependent on the concentration of the Pb^{++} ions, and if the latter be, through any cause,

diminished, the amount of undissociated $PbSO_4$ must be diminished also, with the result that the total amount of lead passing into solution will be less. This was experimentally verified by using the same artificial water as in the last-mentioned experiment, excepting that by the addition of Na_2CO_3 , the free carbonic acid was reduced to about 9.5 mgms. CO_2 per litre, and the $NaHCO_3$ consequently raised to about 128 mgms. per litre, with the result that the lead taken up amounted to only 1.3 mgm. per litre of water.

Experience has also shown that some waters act powerfully on lead when the pipes are charged intermittently, whilst the action becomes very much diminished if they are kept under constant pressure. The effect of pressure on the activity ought, therefore, always to be specially determined (P. F. Frankland, *J. Soc. Chem. Ind.* 1889).

In investigating the action of water on lead, the water should either be put in contact with strips of the metal or placed in leaden pipes for a definite period of time, after which it should be removed and tested for lead both in solution and suspension, fresh portions of the water under examination are then placed in contact with the metal and again tested after a definite interval of time, this procedure being repeated a number of times. Thus it is often found that a water has a considerable initial action on the metal, but as the latter becomes coated with deposit, the action moderates and may practically cease altogether. Some waters, on the other hand, act continuously on the metal.

Some polluted waters have a very strong and continuous action on lead (*Riv. Pollut. Commiss.* 6th Rep. 226), and in such cases the obvious remedy is the abandonment of the source.

It is worthy of note that hot water generally acts much more violently on lead than cold, and further that the lead dissolved in water is entirely removed by passage through any of the numerous forms of animal charcoal filters.

As regards the quantity of lead in water from which danger to health is to be apprehended, it is now generally admitted that water containing anything above one-twentieth grain of lead per gallon, or 0.07 part per 100,000, may, by continued use, produce mischief.

Of the action of water on zinc but little is known beyond the fact that many waters do act on it, and that it is therefore not to be recommended for the construction of cisterns, &c., in which drinking water is to be stored. The solution of the zinc takes place with special facility if metallic iron is also in contact with it (*Heaton, Chem. News*, 49, 85; P. F. Frankland, *ibid.* 115; Stevenson, *ibid.* 107).

Copper appears to be continuously acted on by water, especially if simultaneously in contact with air, and hence should not be used in connection with drinking water.

The action of water and other liquids on aluminium is now a matter of some importance owing to its use for domestic and industrial purposes (see *An Investigation of Aluminium, with Special Reference to its Suitability for the Construction of Brewery Plant*, A. C. Chapman, *J. Inst. Brewing*, 1911). Although acted on by moist air the layer of oxide exerts a marked protection to further attack; alkalis and alkali

chlorides increase the tendency to corrosion. Chapman considers that it may be safely used for the construction of brewing plant, especially fermenting tuns and vessels intended for the treatment of chilled and filtered beers.

THE CHEMICAL ANALYSIS OF WATER.

As the qualitative analysis of the ingredients of water is of no practical importance, and involves no special methods, the quantitative examination will alone be considered here. In order that the analysis may be of any value, especially for sanitary purposes, it is of the greatest importance that the samples should have been collected with care.

Suspended matter.—The suspended matter, if considerable in amount, should be separately determined, but if only present in minute quantity it is advisable to regard it as part of the dissolved matter, in which case it is necessary that the sample should be well shaken before taking out each portion for analysis, so that the suspended particles may be uniformly distributed. If it is decided to determine the suspended matter separately, the sample should be well shaken, and 250 or 500 c.c. measured out and passed through a filter previously dried at 100° and weighed. The matter on the filter is washed with distilled water, and dried at 100° until of constant weight. Some analysts prefer to dry at 105° , 110° , or even 120° , but in all cases the temperature should be specified. The filter and its contents are then incinerated in a coil of platinum wire and dropped into a weighed platinum crucible, gently ignited until free from organic matter, and then treated with a few drops of a solution of ammonium carbonate, and dried at 150° . The loss in weight represents organic matter and water of hydration. It is sometimes of importance to determine the proportion of carbon to nitrogen in the organic part of the suspended matter. For this purpose some of the suspended matter is collected on an ignited plug of asbestos or glass wool, transferred to a small flask, and boiled with 20 c.c. of sulphurous acid and some distilled water free from ammonia and organic matter, and then further treated, as in the determination of organic carbon and nitrogen, by the combustion process (p. 402). If the suspended matter has been thus separately determined, the remainder of the analysis should be performed on the water, after filtration through Swedish paper, rejecting the first 250 c.c. which pass through; or if the suspended matter completely settles on standing the clear water may be siphoned off. The suspended matter may, of course, in exceptional cases also have to be submitted to a complete mineral analysis, or examined for some special ingredient.

An ingenious method of determining minute traces of suspended matter has been devised by Dibdin (*Analyst*, 1896, 21, 2). In this method the volume of the moist suspended matter is measured in a capillary tube.

MATTERS IN SOLUTION.

Total solids.—250 or 500 c.c. of the water are evaporated to dryness in a weighed platinum dish on a water- or steam-bath, the dish being

supported on a glass or porcelain, but not on a metallic, ring. The dish and residue are then dried until constant at 100°, 105°, 110°, 120°, or even at 180°. The residue may be further utilised for the determination of nitrates and nitrites by the mercury method (*v. infra*).

Ammonia.—A measured volume of the water (varying from 100–1000 c.c., according to the proportion of ammonia present) is distilled in a capacious flask or retort connected with a Liebig's condenser, about 1 gm. of recently ignited sodium carbonate having been previously added. It is essential that the whole apparatus should have been carefully freed from ammonia immediately before use, which can be done by distilling some water in the apparatus until the distillate gives no reaction with Nessler solution. The remainder of the water in the flask or retort is then thrown away, and the measured quantity of the sample under examination introduced along with the sodium carbonate. The distillation should be carried on briskly, and the distillate collected in colourless glass cylinders of 50 c.c. capacity. If less than 500 c.c. has been used, this volume should be made up with distilled water free from ammonia before distillation. If the quantity of water has been well chosen, the whole of the ammonia will be found in the first three cylinders of the distillate, and in most cases it will all be contained in the first. The quantity of ammonia in each cylinder is estimated by adding 1 c.c. of Nessler solution, and comparing the coloration obtained with that similarly produced by known quantities of a standard solution of ammonium chloride, added to 50 c.c. of distilled water free from ammonia. The Nessler reaction is so delicate that by its means 1 part of NH_3 in 100,000,000 parts of water can be easily detected. The colour produced by more than 10–15 c.c. of a solution of NH_4Cl (containing 0.00001 gm. NH_3 per litre) is too deep for accurate comparison, and should one of the cylinders require more than this the determination must be repeated on a smaller volume of water. This may be generally avoided, however, by adding the Nessler solution to the second and third cylinders of distillate before the first, and if it is found that the second cylinder gives a colour requiring more than 5 c.c. of the above solution of ammonium chloride for its imitation the first cylinder should be diluted, and an aliquot part taken for testing with the Nessler reagent.

The Nessler solution is prepared by dissolving 62.5 grms. of potassium iodide in 250 c.c. of distilled water; set aside 10 c.c. of this, and run into the remainder a cold saturated solution of mercuric chloride until a permanent precipitate is formed, then add the above 10 c.c. of potassium iodide, which will cause its solution, after which very carefully add more of the mercuric chloride until a slight precipitate remains on stirring. Now add 150 grms. of potassium hydroxide dissolved in distilled water, and dilute the whole to 1000 c.c. After settling, decant the clear liquid into a bottle for use.

As the 'albuminoid ammonia' is commonly determined in one operation with the 'free' ammonia, the method of estimating the former will now be described, instead of considering it under the methods for determining organic matter, where it more properly belongs.

'Albuminoid ammonia' process.—Whilst the determination of the free ammonia is being proceeded with as above, the solution of alkaline permanganate must be prepared for this process, as it is required immediately the free ammonia has passed over. The volume of the alkaline permanganate (for preparation *v. below*) taken must be at least one-tenth of the volume of the sample being distilled for ammonia, and it should not exceed that volume unless the water contains a very large amount of organic matter. The alkaline permanganate taken is then diluted with four times its volume of distilled water, and boiled in a flask during the whole of the time that the distillation for free ammonia is going on as above, and when the latter is finished it is added to the water remaining in the distilling flask or retort (the whole volume in this must now be not less than 500 c.c.), and distillation is then continued until the distillate is free from ammonia. The distillate is collected and Nesslerised, as in the determination of free ammonia above. The ammonia thus evolved by distillation with alkaline permanganate is generally recorded as 'albuminoid ammonia' (*v. 403*). The alkaline permanganate solution is prepared by dissolving 200 grms. of potassium hydroxide and 8 grms. of pure potassium permanganate in 1100 c.c. of distilled water, then boiling the solution rapidly until concentrated to about 1000 c.c.

Chlorine.—(a) *Mohr's method.* 50 or 100 c.c. of water are treated with a few drops of a solution of potassium chromate, and a standard solution of silver nitrate is then run in from a burette until the precipitate becomes of a faint but distinctly red colour. The water must be well agitated after each addition of the nitrate, the reaction depending upon the decomposition of the red silver chromate by dissolved chlorides with formation of silver chloride and soluble chromate. As soon as the last trace of chloride is precipitated as silver chloride, the red colour of the silver chromate makes its appearance. By using a solution of silver nitrate containing 2.3944 grms. per litre, the number of c.c. employed gives at once (if 50 c.c. of water have been taken) the parts of Cl per 100,000, whilst if 100 c.c. of water are taken the silver nitrate solution should be of double this strength.

Mohr's method cannot be employed if the water is acid, and if this is the case a given volume of the water should be boiled with an excess of pure calcium carbonate (free from chlorides), filtered, the filtrate made up to known volume, and the chlorine determined in a part of this. In the presence of reducing substances, much organic matter, sulphuretted hydrogen, and sulphites, the method is also inapplicable, and in such cases it is desirable to determine the chlorine gravimetrically, which should also be done if the proportion of chlorine is large.

(b) *Folhard's method.* 50 or 100 c.c. of the water are treated with an excess of decinormal silver nitrate, the mixture being well agitated so as to cause the silver chloride to settle in flakes; the latter is filtered off and washed, and then to the filtrate about ten drops of a cold saturated solution of iron-alum are added, and subsequently enough strong nitric acid (free from nitrous acid) to remove the colour of the ferric

salt. Decinormal ammonium thiocyanate is then added from a burette, stirring well all the time, until the liquid acquires a light yellow-brown colour, which remains permanent on leaving the liquid at rest for about 10 mins. By deducting the number of c.c.'s of thiocyanate from that of the silver nitrate added, the remaining silver nitrate indicates the proportion of chlorine present in the water. The advantage of this method consists in its being applicable to acid liquids. The method depends upon there being no formation of red ferric thiocyanate until the whole of the silver in solution has been precipitated as thiocyanate (*Annalen*, 190, 24).

Nitrogen as nitrates and nitrites.—A number of different methods have been devised for the determination of oxidised nitrogen; there are, however, only a few which have been largely adopted in practice, and such alone will be described here.

(a) *Crum's method.* This depends on the decomposition which nitrates and nitrites undergo when dissolved in strong sulphuric acid on being shaken up with mercury, and which leads to the evolution of the whole of the nitrogen as nitric oxide, the volume of which is then determined. The residue obtained in the estimation of the total solids (*see p. 395*) may be conveniently used for this determination also. This residue in the platinum or glass dish is repeatedly treated with a very small quantity of hot distilled water, which is brought into thorough contact with the residue by detaching the latter with a small glass rod covered with a piece of india-rubber. The aqueous extracts, which should in all not exceed about 10 c.c., are passed through a small filter and collected in a little beaker. This aqueous extract, containing all the soluble salts in the water residue, is evaporated nearly to dryness on a water-bath, after which it is dissolved again in a minimum quantity (1 or 2 c.c.) of water, and introduced into a Lange nitrometer (*Ber. 11, 434*); the beaker is repeatedly rinsed with a few drops of hot water, and these rinsings added to the nitrometer. The beaker is then further rinsed with pure strong sulphuric acid (free from oxides of nitrogen), and this also is transferred to the nitrometer. About $1\frac{1}{2}$ volumes of sulphuric acid must in all be used to 1 volume of aqueous extract. If the water contains soluble carbonates there will be an evolution of carbon dioxide when the sulphuric acid mixes with the aqueous extract; the gas should be allowed to collect without shaking the tube, and should then be expelled. The contents of the nitrometer tube are now violently agitated with the mercury, and then in the course of a minute or so the evolution of nitric oxide will commence, and the agitation should be continued as long as any gas continues to come off. If the water contains a considerable quantity of chlorides some hydrogen chloride may have been given off with the nitric oxide, but this may be removed by admitting a little water into the nitrometer. When the gas has cooled to the temperature of the air, its volume is measured at atmospheric pressure. The determination is rendered more accurate, especially if the quantity of nitrates and nitrites is only small, by measuring the nitric oxide in Frankland's gas apparatus, in

which case the decomposition with mercury and sulphuric acid is effected in a small tube standing in a mercury trough, the evolved nitric oxide being then transferred to the gas apparatus (*see Sutton's Volumetric Analysis*). This method, which is by far the most convenient for ordinary water analysis, becomes inapplicable in the presence of very large quantities either of organic matter or of chlorides.

(b) *Methods of Schloësing-Tiemann, and of Schloësing-Reichardt,* depend upon the decomposition of nitrates and nitrites by ferrous chloride and hydrochloric acid, and the measurement of the evolved nitric oxide. Of these methods, which closely resemble each other, the former, as the more convenient, need alone be considered here.

100–500 c.c. of the water are concentrated by evaporation to about 50 c.c., which are then introduced into a flask of about 150 c.c. capacity, provided with an india-rubber stopper, perforated by two narrow pieces of glass tubing, of which one (A) extends about an inch into the flask, and is constricted below, whilst the other (B) only just penetrates the stopper; the tube (B) is externally connected by means of a short piece of india-rubber tubing provided with a pinch-cock, with a delivery tube dipping into a trough containing 10 p.c. caustic soda solution previously boiled to expel air. The tube (A) is also connected with india-rubber and pinch-cock to another piece of glass tubing, which is allowed to hang vertically downwards. The water in the flask is vigorously boiled with the pinch-cocks open until the air is completely expelled by the steam, then the pinch-cock on (B) is closed whilst that on (A) is left open until the volume of water in the flask is reduced to about 10 c.c.; this pinch-cock is then also closed, and the flame removed from beneath the flask. The glass tube attached to (A) is carefully filled with water up to the pinch-cock; 15–20 c.c. of a saturated solution of ferrous chloride are introduced into the flask, in which there is now a partial vacuum, by siphoning from a small beaker through (A), the pinch-cock being temporarily opened, and about an equal quantity of strong hydrochloric acid is made to follow in the same manner into the flask. The flask is now carefully heated, and when the internal pressure rises the pinch-cock on (B) is opened, and the evolved gas allowed to pass through the delivery tube into a measuring tube filled with the 10 p.c. caustic soda solution standing in the trough. The heating of the flask is continued until the volume of gas in the measuring tube ceases to increase. The measuring tube is transferred to a tall glass cylinder full of water, and after the gas has acquired the temperature of the room the volume is measured at the atmospheric pressure, a correction being of course made for the tension of aqueous vapour.

This method is specially applicable to the case of water containing excessive quantities of organic matter and chlorides (*Ber. 1873, 1041*; Tiemann and Gärtner's *Untersuchung d. Wässern*, 170).

For Schloësing-Reichardt's method, *v. Zeitsch. anal. Chem.* 1870, 24, or Tiemann and Gärtner's *Untersuch. d. Wässern*, 175.

(c) *The aluminium and zinc copper methods* depend upon the conversion by means of

hydrogen of the oxidised nitrogen in the water into ammonia, and estimation of the latter by Nessler solution.

Aluminium method.—100 c.c. of the water are introduced into a flask together with 10 c.c. of caustic soda solution free from nitrates and nitrites, the mixture being boiled until it is reduced to about one-fourth of its volume. It is then diluted to about its original bulk with distilled water free from ammonia, and a piece of aluminium foil, about 2 ins. square and wrapped round a piece of glass rod, is dropped into the flask, which is then fitted with a stopper and small U-tube containing glass beads moistened with hydrochloric acid free from ammonia. After the evolution of hydrogen has continued for about 6 hours, the glass beads and washings of the U-tube are transferred to the liquid in the flask, the latter is then attached to a Liebig's condenser, and the ammonia determined by distillation and Nesslerising in the ordinary way (see p. 396). According to Tiemann and Gartner (*Untersuchung des Wassers*, 208), only the equivalent of 72–90 p.c. of the nitric acid is thus recovered as ammonia.

Zinc-copper couple method.—The residue obtained in the determination of 'total solids' is extracted with about 25 c.c. of hot distilled water, and this is boiled down with a fragment of recently-ignited pure lime about the size of a hemp-seed to one-fourth of its bulk. This liquid, together with the washings of the dish containing the residue, is transferred through a stoppered funnel into an eight-ounce Wurtz flask, attached to a Liebig's condenser, and containing the requisite amount of the zinc-copper couple. The distillation is carried on until the greater part of the water has passed over, after which hot distilled water is repeatedly run into the flask and the distillation continued until about 100 c.c. of distillate have been collected; the latter is then 'Nesslerised' in the ordinary way (Thorpe, *Chem. Soc. Trans.* 1873, 541). According to Tiemann and Gartner, from 88 to 95 p.c. of the nitric acid is thus obtained.

In the writer's laboratory the process is carried out as follows: A stoppered bottle (about 200 c.c. capacity) is loosely filled with strips of zinc, which, after cleaning with dilute sulphuric acid, are covered with copper sulphate solution (1 p.c.). The copper-coated strips are repeatedly washed with distilled water, and finally with the water under examination, care being taken not to detach the copper film. The bottle is then completely filled with the sample of water and a crystal of oxalic acid is added, and the bottle, loosely stoppered, is allowed to stand over night. A definite volume is withdrawn by means of a pipette, and this is distilled with a suitable volume of ammonia-free water in the ammonia apparatus as usual, a small quantity of ignited sodium carbonate being added. Before withdrawing the water from the bottle for distillation, a small quantity should be tested for nitrite to ensure that the reduction to ammonia is complete. Waters containing free or saline ammonia must have this distilled off before being placed in contact with the zinc-copper couple.

A rapid method of estimating nitrates in water is due to Harrow (*Chem. Soc. Trans.* 1891, 395), depending on the reduction to nitrite

by zinc-dust and estimation of the nitrous acid by sulphanilic acid and α -naphthylamine (Griess test). This reagent is prepared by dissolving 1 grm. of α -naphthylamine, 1 grm. sulphanilic acid, and 25 c.c. strong hydrochloric acid in about 200 c.c. distilled water; boiling with a small quantity of animal charcoal, filter, and making up to 500 c.c. The process is conducted thus: 50 c.c. of the water are placed in a beaker of 100 c.c. capacity, and in three similar beakers 50 c.c. of three standard solutions of potassium nitrate, containing (1) 1.0 part N, (2) 0.1 part N, (3) 0.01 part N per 100,000; to each beaker 10 c.c. of the above test-solution are added, and afterwards a very small quantity (7–8 mg.) of zinc-dust. If nitrate is present in the water a pink colour appears, which must be compared with that yielded by the three standard solutions after 15 mins. This gives an approximate idea of the amount of nitrate present, whilst in order to obtain an accurate result the water must be diluted until the colour produced is almost identical with that given by one of the standards. The results appear to be accurate, but it is especially necessary to avoid the addition of large quantities of zinc-dust, which would decolorise the solution.

(d) *The indigo method* differs from those previously described in being a simple volumetric method depending upon the decolorising action of nitric acid on indigo solution. The results are only accurate when the greatest uniformity is preserved in the conditions under which the experiments are made—the process is, in fact, entirely empirical. It may be carried out as follows: 25 c.c. of the water are mixed with 50 c.c. of pure strong sulphuric acid; a dilute solution of indigo is then immediately added from a burette, shaking the whole time, until the solution acquires a bluish-green colour. In a second experiment nearly the whole volume of indigo which was found necessary in the first experiment is added at once, and the blue colour is then obtained by further small additions, and in this manner, by shortening the time taken in the titration, a more accurate result, generally higher than in the preliminary experiment, is obtained. The solution of indigo must be standardised under precisely similar conditions by means of a solution of potassium nitrate of known strength. The indigo solution should be chosen of such strength that 6–8 c.c. correspond to 0.001 grm. N_2O_5 ; and if 25 a.c. of the water contains more than 0.003–0.004 grm. N_2O_5 , it should be diluted before a final titration is made. The method is only suitable for use by an operator in continual practice (Warington, *Chem. Soc. Trans.* 1879, 578; *Water Analysis*, E. Frankland, 31). The results are too low if there is a large amount of organic matter in the water.

The methods described above do not distinguish between nitrous and nitric acids. Indeed, the indigo method is altogether unreliable in the presence of any notable proportion of nitrous acid, as is also Cram's method, should it be necessary to allow any carbon dioxide to escape before shaking with mercury (see p. 397). As nitrous acid is, however, generally only present in natural waters in minute traces, these difficulties do not frequently arise, and the

which may be most conveniently estimated by colorimetric methods, of which there are several in vogue. Of these may be mentioned:

(a) *Preuss-Tismann's method*, depending upon the production of Bismarck brown when an acid solution of a nitrite acts upon *m*-phenylenediamine. 100 c.c. of the water are placed in a colourless glass cylinder, 1 c.c. of dilute sulphuric acid (1 : 3) is added, and then 1 c.c. of solution of *m*-phenylenediamine (5 grms in 1000 c.c. distilled water, decolorised if necessary with animal charcoal); if the colour appears in less than 1 or 2 mins. the experiment must be repeated with a smaller quantity of water, in each case diluted, however, to 100 c.c. The coloration is then imitated under precisely similar conditions with a standard solution (the standardisation can be effected either by the potassium permanganate, or, better, by the urea method) of potassium or sodium nitrite. The final tint is not arrived at until the mixture in the glass cylinder has stood for 20-25 mins., which is the great drawback of the process (see also Warington, *The Detection of Nitric and Nitrous Acids*, Chem. News, 1885, 51, 39).

A preferable method (Zambelli, Chem. Soc. Abstr. 1887, 533) consists in adding to the water a few drops of a saturated solution of sulphuric acid in dilute sulphuric acid, then a few drops of a saturated aqueous solution of phenol, after which the mixture is rendered alkaline with ammonia. The presence of nitrous acid is indicated by the appearance of a coloration, varying from faint yellow to intense reddish yellow, according to the quantity of nitrous acid present. The author claims that this method is capable of revealing the presence of 1 part of nitrous nitrogen in 40,000,000 parts of water. It has the great advantage that the reagents employed are permanent in solution.

For larger quantities of nitrous acid, as also for the standardisation of solutions of sodium and potassium nitrite, the urea method devised by the writer is to be recommended (Chem. Soc. Trans. 1888, 364).

Hardness.—The determination of the hardness of a water consists in empirically ascertaining the amount of soap which has to be destroyed by a given volume of the water before a lather can be obtained, and expressing this in terms of the amount of calcium carbonate which must be dissolved in the same volume of water to destroy the same amount of soap. Accurate results can only be obtained by preserving uniformity in the conditions of experiment.

50 c.c. of the water are measured into an 8-oz. stoppered bottle, which is then violently agitated and the air sucked out by means of a glass tube to remove any carbon dioxide which may be given off by the water. A standard solution of soap (*v. infra*) is then added in diminishing quantities not exceeding 0.5-0.10 c.c. at a time, even at first, violently shaking after each addition, until the froth produced remains unbroken over the surface for a period of 5 mins. when the bottle is placed at rest on its side. The quantity of calcium carbonate corresponding to the volume of soap solution employed can then be ascertained by reference to the empirical table which follows.

Table of hardness in parts per 100,000, 50 c.c. of water being used.

G.c. of soap solution	CaCO ₃ per 100,000	G.c. of soap solution	CaCO ₃ per 100,000	G.c. of soap solution	CaCO ₃ per 100,000

In performing the titration as above, the experienced operator is guided by the ear as well as by the eye, for the sound produced on shaking serves to indicate how the reaction between the hardening constituents of the water and the soap is progressing, for as this approaches completion the sound becomes softer, and when an excess of soap has been added the agitation is all but noiseless.

In the case of waters requiring more than

16 c.c. of soap solution for the 50 c.c. of water, it is necessary to take a smaller volume of the water and dilute to 50 c.c. with boiled distilled water. The presence of magnesia salts is indicated in the soap test by the formation of a characteristic light curd, and also by the premature formation of a lather, which again disappears on the further addition of soap solution and shaking. If these signs are exhibited, only such a volume of water should be taken as, when diluted to 50 c.c., requires not more than 7 c.c. of the soap solution; indeed, it is a very good practice invariably to dilute waters so that not more than 7 or 8 c.c. of soap solution are required. In the presence of magnesia salts the results are always less accurate, and, unless great care is exercised, may become wide of the truth.

Permanent hardness.—The permanent hardness is most conveniently determined by taking a small flask with a *very short neck* (the Erlenmeyer shape is very suitable), and adding the water to it until a definite weight (e.g. 250 grms.) has been made up. The water is then maintained in gentle ebullition for exactly half-an-hour, and, after cooling, the weight is again made up to the original by the addition of boiled distilled water, the soap titration being then performed on a measured portion of this, as described above.

Some analysts prefer to take a given volume of water and restore the volume after boiling, then removing the precipitated carbonates of lime and magnesia by passing through a dry filter.

The *standard solution of soap* is prepared as follows. A cake of Castile soap is scraped with a knife, and about 7 grms. of the shavings are dissolved in 500 c.c. of a mixture of 2 vols. of methylated spirit with 1 vol. of distilled water. Filter off the insoluble matter, and dilute the soap solution with half its volume of water. A portion of this solution is then further carefully diluted with a mixture of 2 vols. methylated spirit and 1 vol. water until 7·8 c.c. are required to form a permanent lather with a mixture of 25 c.c. of the standard calcium chloride solution (prepared by dissolving 0·2 gm. of Iceland spar in dilute hydrochloric acid, and, after driving off excess of acid on the water-bath, making up to 1000 c.c. with distilled water) and 25 c.c. of distilled water.

Poisonous metals.—Of these the only ones which are of practical importance in water analysis are lead, zinc, copper, arsenic, and barium. As they are generally present in only very minute proportions, it is necessary to evaporate large volumes (5 litres and upwards) of water in order to obtain gravimetric determinations in the ordinary way; but the following special methods may be generally employed.

For *lead*, take 100 c.c. of the water, acidify with a few drops of acetic acid, and then add about 5 c.c. of a saturated solution of sulphuretted hydrogen. The colour produced is imitated by adding a known quantity of a standard solution of a lead salt to 100 c.c. of distilled water. Even such small proportions as 0·03 part Pb per 100,000 should invariably be recorded. (For the standard solution of lead, dissolve 0·1831 gm. crystallised normal lead acetate in 1000 c.c. distilled water; 1 c.c.=0·0001 Pb.)

For *copper*, the same colorimetric method may be employed as for lead, using for comparison a solution of copper sulphate containing 0·0001 gm Cu in 1 c.c. (0·3929 gm. crystallised copper sulphate per litre). In the absence of iron a very delicate colorimetric method may be employed, based upon the reaction between copper salts and potassium ferrocyanide, the water being acidified with hydrochloric acid, whilst in the presence of iron the blue coloration produced by ammonia may be used.

The presence of *zinc* is generally indicated by the gradual formation of a film of carbonate on the surface of the water when the latter is exposed to the air. Some of this film ignited on platinum foil should leave a residue, which is yellow when hot and white on cooling. The quantity of the zinc may be approximately determined, in the absence of other heavy metals, by acidifying 100 c.c. of the water with dilute hydrochloric acid, and then adding a solution of potassium ferrocyanide. The white turbidity produced is then compared with that obtained from a known quantity of a standard solution of a zinc salt (Snijders, Ber. 1878, 939).

Arsenic is best detected and estimated by Marsh's test; 500 c.c. of the water are rendered slightly alkaline with caustic soda or potash free from arsenic, and evaporated to dryness. The residue is extracted with strong hydrochloric acid, and the liquid introduced into a Marsh's apparatus. The gas is passed through a small U-tube containing pumice soaked in solution of lead acetate, and then through a piece of combustion tube constricted in the middle, where it is heated to redness. The passage of gas through the heated tube is continued for an hour, although nearly all the arsenic is liberated in 5 or 10 mins. The metallic ring formed is compared with a number of standard rings similarly obtained with known quantities of arsenic. A blank experiment must invariably be performed previously, to control the purity of the chemicals employed.

Barium may be detected and determined by concentrating a considerable volume of the water, acidifying with hydrochloric acid, and after filtering, if necessary, adding a solution of calcium sulphate. The barium sulphate precipitated is then collected and weighed in the ordinary manner.

Iron can generally be estimated colorimetrically by means of ferrocyanide or thiocyanate. Its determination is frequently of importance in waters used for industrial purposes.

In the ferrocyanide method, the water residue is dissolved in hydrochloric acid and diluted to 100 c.c. Of this 10 c.c. are transferred to a 100 c.c. cylinder; add 1 c.c. of strong nitric acid, dilute to 100 c.c., stir, and then add 1 c.c. of potassium ferrocyanide solution and mix well. The colour produced is compared with that obtained from a standard iron solution, but the same quantity of nitric acid must be present in each case (Sutton, Volum. Analys. 6th ed. 194; v. also Carter Bell, J. Soc. Chem. Ind. 8, 175).

In the thiocyanate method, two 100 c.c. cylinders are taken, and into each 5 c.c. of dilute hydrochloric acid (1 : 5) and 5 c.c. of dilute nitric acid (1 : 5), together with 15 c.c. of thiocyanate solution, are poured; then introduce a

measured volume of the liquid to be tested into the one cylinder, and after filling up both cylinders to the mark with distilled water, imitate the red colour obtained with the liquid under examination by running in a standard solution of iron from a burette into the other cylinder. In this way one part of iron is said to be recognisable in fifty millions of water (Thompson, Chem. Soc. Trans. 1885, 493).

Determination of organic matter.—A number of processes have been devised for the determination either of the whole or part of the organic substances present in water. Of those which lay claim to discovering the whole of these organic materials, none is entitled to any confidence, whilst even those which attempt to determine a part, or to indirectly obtain a comparative measure of the organic matter, are also open to objections on the score of accuracy. Only those methods more commonly in use by water analysts will be described here.

(1) *Methods depending on the reduction of potassium permanganate.*

(a) *Kubel's process.*—In this the reduction is effected in acid solution. 100 c.c. of the water are placed in a flask of about 300 c.c. capacity and treated with 5 c.c. dilute sulphuric acid (1 : 3), and then with such a quantity of standard dilute permanganate (equivalent to centinormal oxalic acid) that the liquid is of a strong red colour. The mixture is then boiled for 10 mins., and the excess of permanganate added must be such that the colour is not discharged in the operation. 10 c.c. of centinormal oxalic acid are now added, and into the resulting colourless liquid standard permanganate is then run until a faint red colour is obtained. The amount of oxygen consumed by the organic matter in the water can then be calculated.

(b) *Schulze's process.*—In this the reduction is commenced in an alkaline and completed in an acid solution. 100 c.c. of the water are placed in a flask of about 300 c.c. capacity, 0.5 c.c. caustic soda solution (1 : 2) are added, as well as 10–15 c.c. of standard dilute permanganate (equivalent to centinormal oxalic acid). The liquid is boiled for 10 mins., allowed to cool to 50° or 60°C. and then 5 c.c. of dilute sulphuric acid (1 : 3) and 10 c.c. of centinormal oxalic acid are added, the liquid being shaken and gently warmed until the colour has quite disappeared. Then the standard dilute permanganate is run in until a faint red colour, remaining permanent for at least 5 mins., is obtained. The oxygen consumed by the organic matter of the water is then calculated.

(c) *Forchhammer process.*—This resembles Kubel's method, inasmuch as the reduction of the permanganate is effected in an acid solution, but the temperature employed, instead of being defined, is that of the air of the laboratory.

Two flasks are carefully cleaned and into one 250 c.c. of the water, into the other 250 c.c. of distilled water, are introduced. To each 10 c.c. of dilute sulphuric acid (1 : 3) and 10 c.c. of standard permanganate (containing 0.395 gm. per litre or 0.001 gm. available oxygen in 10 c.c.) are added, and the mixture is allowed to stand for three hours. At the end of this time the excess of permanganate remaining is deter-

mined by adding two drops of potassium iodide (1 : 10) to each flask, and then running in a standard solution of sodium thiosulphate (1 gm. per litre) until the whole of the free iodine is removed, a drop of clear starch solution being added at the close of the operation. The amount of permanganate destroyed in the blank experiment must of course be deducted from that destroyed in the case of the water, and from the difference the oxygen consumed by the organic matter of the water can be calculated (Tidy, Chem. Soc. Trans. 1879, 66).

In this country it is now almost the invariable custom of water analysts to allow the acid permanganate to act for 4 hours at 80°F. (26.7°C.); Thorpe (Metropolitan Water Reports, 1904) has also used 1 hour at 122°F. (50°C.), under which conditions a larger amount of oxygen is consumed.

It must be pointed out that in these several methods depending on the reduction of permanganate, the results are only comparative for the same kind of organic matter, a given weight of organic carbon in different kinds of water consuming different quantities of oxygen from permanganate under the same conditions. Thus it has been found that for surface waters, such as those of the rivers Thames and Lea, by multiplying the oxygen consumed in the Forchhammer process by the factor 2.38, the proportion of organic carbon (as determined by combustion) is approximately obtained, whilst in the case of deep well water the factor which must be employed is 5.8 (Woodland Toms).

Again, all these methods are affected by the presence of nitrites, ferrous salts, and larger quantities of ammonia compounds, all of which exercise a reducing action on permanganate. By determining the nitrous acid, a correction can be made for this, whilst the ferrous can generally be converted into ferric iron by shaking up the water several times in a half-filled bottle previously to the oxidation with permanganate; and the error due to ammonium salts is so small that it can generally be neglected (even one part NH_3 per 100,000 has no appreciable reducing effect) (Preusse and Tiemann, Ber. 12, 1906).

(2) *Determination of organic carbon by oxidation of organic matter with potassium dichromate and sulphuric acid* (Wolff, Degener, and Herzfeld).—500–1000 c.c. of the water are introduced into a capacious retort, the neck of which is drawn out and bent downwards and is connected with a Liebig's condenser. This arrangement enables the retort to be turned upwards and the condenser downwards, thus preventing any loss by spurting during distillation, which is carried on until 250–700 c.c. (according to the volume of water employed) have passed over. The distillate is submitted to Kubel's method (*u. supra*) to ascertain whether any volatile organic matters are present. Alkaline waters should be saturated with carbon dioxide, and acid waters carefully neutralised with sodium carbonate before the above distillation. The water remaining in the retort is evaporated down to 15 c.c. in a glass dish on a water-bath, the access of dust being carefully avoided. This concentrated liquid is introduced into a flask of 250–300 c.c. capacity, and the dish and retort are rinsed with 10 c.c. of dilute sulphuric acid (1 : 3),

these rinsings also being added to the water in the flask. The decomposition of carbonates caused by the addition of this acid is completed by heating to 50°C. and shaking, and the evolved carbon dioxide completely displaced by air. After cooling the flask and its contents, 10 grms. of finely-powdered potassium dichromate are added, and the flask is then attached to the remainder of the apparatus. An india-rubber stopper with three holes is placed in the flask; through one hole passes a thermometer dipping into the liquid, through a second passes nearly to the bottom of the flask the tube of a bulb-funnel (A) provided with a stopcock, whilst through the third passes the bent tube of an inverted Liebig's condenser (B). The upper extremity of the condenser (B) is connected with two U-tubes (C and D) filled with fused calcium chloride, whilst between these is a third U-tube (E) containing coarsely-powdered antimony. Of these, C and D are intended to absorb the moisture passing the condenser, and the intermediate one, E, to retain any chlorine. Following on these tubes is a set of weighed potash-bulbs (F) for the absorption of carbon dioxide, and these bulbs are, of course, protected from ingress of moisture on the other side by means of a calcium chloride tube, which can be attached to an aspirator at the close of the experiment. The apparatus having been thus put together, 50-60 c.c. of diluted sulphuric acid (3:2) are gradually added through the stoppered funnel (A). During the first half-hour the temperature is kept at 50-55°C., whilst during the second half-hour it is gradually raised to boiling, which is maintained from 5-10 mins. The aspirator is then attached, the air which enters by the funnel (A) having been previously freed from carbon dioxide by bubbling through caustic potash. The increase in weight of the potash bulbs (F) gives the weight of carbon dioxide evolved, from which the carbon itself can be calculated (Ber. 1886, 2618; Tiemann-Gärtner, *Untersuch. d. Wassers*, 247).

For a somewhat similar method of determining organic carbon in which permanganate is used instead of dichromate, see Blair, *Organic Analysis of potable Waters*, Churchill, 1891, 83. The method appears worthy of more extended trial.

(3) *Determination of organic carbon and nitrogen by combustion.*—(a) *Frankland and Armstrong's process* (Chem. Soc. Trans. 6, 77). This method, which is unquestionably the most rational and exact, has been adopted to a comparatively limited extent by water analysts in consequence of the special apparatus and manipulative skill which it entails. The method will be described only in outline here, and for full particulars the reader is referred to Sutton's *Volumetric Analysis*, whilst for a critical survey of the methods employed in the organic analysis of water he should not fail to consult Mallet, *Report of the United States National Board of Health*, 1882.

The process is divisible into three parts: (1) the evaporation of the water, (2) the preparation and combustion of the residue thus obtained, and (3) the measurement of the gases evolved in the combustion.

For the evaporation, from 100 c.c. (in the case of sewage and highly polluted waters) to

1000 c.c. (in the case of very pure waters) are measured into a clean flask, 20 c.c. of a saturated solution of sulphurous acid being added together with a drop of a solution of ferric chloride; the liquid is then boiled rapidly for a few seconds. This treatment secures the decomposition of carbonates, nitrates, and nitrites, whilst any ammonia is fixed by the sulphurous acid, and this ammoniacal nitrogen, which has previously been determined, must be deducted from the total amount of nitrogen obtained in the combustion. The water is now rapidly cooled, and the evaporation commenced in an apparatus specially designed for the purpose. This consists of a nearly hemispherical glass dish about 4 ins. in diameter and without a lip. It is floated in a shallow copper basin heated below by a water-bath provided with constant feed, and on the flange of this copper basin there rests a truncated conical ring, constructed of lead or copper, and about 3 ins. in height, whilst upon a flange at the top of this again rests a tall glass shade about 12-18 ins. in height. The water for evaporation is placed in a flask which is provided with a delivery tube of special construction ground on to its neck, and which serves, when the flask is turned upside down, to maintain the water at a constant level in the glass dish in which the evaporation is proceeding, for this delivery tube is made to pass through a notch in the truncated conical metal ring, just beneath the glass shade which the latter supports, and delivers into the centre of the glass dish within. In the writer's laboratory, the evaporation of 500 c.c. of water is found to take from 10-12 hours. The evaporation should be continued until the residue is quite dry, and if the water contains only a small amount of total solids it is advisable to add a little ignited calcium phosphate to the dish before commencing the evaporation. In the analysis of sewage, or waters containing much ammonia and no nitrates or nitrites, it is advantageous to use 10 c.c. of a solution of metaphosphoric acid (1:10) instead of the sulphurous acid, as ammonium phosphate loses much less ammonia during evaporation than ammonium sulphite. A little ignited calcium phosphate should also be added to dry the residue in this case. But if there are no nitrates and nitrites and much ammonia, the more satisfactory, although more laborious, plan is to use a little ignited borax instead of the sulphurous or metaphosphoric acid. In this way the ammonia is completely dissipated on evaporation, and as no correction has, therefore, to be applied to the organic nitrogen found, the result is more correct. But as boric acid does not entirely decompose carbonates the accuracy of the organic carbon found by this method may be seriously affected, and it is advisable to make a separate determination of the carbon in a second experiment in which the sulphurous acid method is employed. Unless this method be adopted the results for organic nitrogen in the presence of much ammonia are nearly sure to be highly inaccurate.

If the water contains more than 0.5 part per 100,000 of nitrogen as nitrates and nitrites, the 20 c.c. of sulphurous acid employed above may not improbably prove insufficient for their complete destruction, and in the case of such waters the residue in the dish should be further treated

with 10 c.c. of sulphurous acid, this evaporated off, and if the amount of nitric or nitrous nitrogen exceed 1 part per 100,000 this treatment of the residue with further quantities of sulphurous acid may be repeated twice or three times to secure complete destruction of the nitrates and nitrites.

The preparation and combustion of the residue thus obtained is effected by thoroughly mixing with the latter in the dish a small quantity of finely divided and carefully ignited copper oxide. This is then completely transferred to a narrow piece of combustion tubing about 18 ins. long and sealed at one extremity. The dish is again rinsed with a little fine oxide, and this also transferred to the tube. Coarse and carefully ignited oxide of copper (preferably from wire) is then introduced to a depth of about 10 ins., whilst the fine oxide previously introduced will occupy about 2 ins. Upon the stratum of coarse oxide follows a copper gauze cylinder 3 ins. in length, and then another layer of coarse oxide about 1 in. long. The open extremity of the tube is now drawn out over the blowpipe, so that it can be connected with a Sprengel mercury pump. The tube is completely exhausted, and the combustion performed *in vacuo* in the ordinary way, the evolved gases being then drawn over by the pump and collected in a test tube filled with mercury and placed over the lower open extremity of the fall tube in the trough below.

The volumetric measurement of the gases (consisting of carbon dioxide, nitrogen, and possibly also nitric oxide and sulphur dioxide) collected as above is carried out in the Frankland gas apparatus, which admits of the measurement of very minute quantities of gas. Three measurements are only necessary. In the first place the gas is treated with a few drops of a saturated solution of potassium dichromate to absorb any sulphur dioxide that may be present. The volume of the gas is then accurately measured, after which it is treated with a few drops of strong caustic potash, which rapidly removes the carbon dioxide, after which the volume of the remaining gas is again carefully ascertained. The residual gas now consists of nitrogen, with possibly a little nitric oxide. It is mixed with a bubble of pure oxygen in order to convert any nitric oxide into nitrous and nitric acids, which are immediately absorbed by the caustic potash present, and then, on adding a drop or two of solution of pyrogallous acid, the excess of oxygen is absorbed and the remaining gas, which consists of nitrogen, is carefully measured. The diminution in volume effected by the caustic potash in the first instance obviously represents the carbon dioxide, whilst the final volume of residual gas, together with one-half of the contraction resulting from the addition of oxygen and pyrogallous acid, represent the total volume of nitrogen. From these volumes the weights of carbon and nitrogen respectively can be calculated. As already pointed out, if sulphurous or metaphosphoric acid has been used in the evaporation, and ammonia is present in the water, the ammoniacal nitrogen (subject to an empirical correction for loss of ammonia during evaporation) has to be subtracted from the total nitrogen found by combustion. A small correction (ascor-

tained by blank experiments made from time to time with the reagents employed in the evaporation and combustion) has also to be applied to the carbon and nitrogen thus determined.

For Dupré and Hake's method, see Chem. Soc. Trans. 1879, 159.

In Dittmar and Robinson's method of determining organic carbon, the gases proceeding from the combustion tube are first passed through a U-tube containing a solution of chromic acid in 60 p.c. sulphuric acid to absorb moisture and sulphurous acid (the water is evaporated with sulphurous acid for the preparation of the residue), the carbon dioxide being absorbed in a weighed soda-lime tube (Chem. News, 1877, 36, 26). A method of determining organic nitrogen has also been devised by Dittmar and Robinson, and is described below.

(4) *Methods for determination of organic nitrogen only.*—Of these the most common one in use is the well-known

(a) '*Albuminoid ammonia*' process of Wanklyn, Chapman, and Smith (Chem. Soc. Trans. 1867, 591), which does not yield the whole, but only very variable proportions, of the organic nitrogen in different nitrogenous organic substances, although in the case of some—such as leucine, aspartic acid, tyrosine, &c.—which frequently appear as decomposition products of albuminous matters, nearly the whole of the nitrogen is obtained as ammonia (Preusse and Tiemann, Ber. 12, 1906; Mallet, U.S. National Board of Health Report, 1882).

The method has already been described on p. 396.

(b) *Dittmar and Robinson's process.*—In this process the residue, obtained in the same way as for the combustion process, is heated with fused caustic soda, or soda and baryta, in a copper or silver boat placed in a combustion tube in a current of hydrogen, the evolved ammonia being absorbed by very dilute hydrochloric acid, which is subsequently 'Nesslerised' (Chem. News, 1877, 36, 26). The results are accurate, and coincide with those obtained by the combustion process of Frankland and Armstrong.

(c) *Kjeldahl's process.*—This well-known and now much-employed method for determining organic nitrogen was adapted for use in water analysis by Drown and Martin (Chem. News, 59, 272). It appears to give accurate results uninfluenced by the presence of nitrates and nitrites in such quantities as are found in ordinary waters, 500 c.c. of the water are placed in a round-bottomed flask of about 900 c.c. capacity; the volume is then reduced to about 200 c.c. by boiling, and to this, after cooling, 10 c.c. of pure concentrated sulphuric acid are added. The mixture is then cautiously boiled, with the flask in an inclined position, until all the water has been driven off and the acid remains of a white or very pale-yellow colour. After removing the source of heat, add a little powdered permanganate until, on shaking, the liquid becomes green, showing that excess has been added. If a purple instead of a green colour appears, it shows that the whole of the water has not been driven off. When cool, 200 c.c. of water free from ammonia are added, care being taken to rinse round the neck of the flask, and thus wash in any acid which may be adhering there.

WATER.

150 c.c. of sodium hydroxide solution are then added, and the mixture distilled with a Liebig's condenser. (The sodium hydroxide solution is prepared by dissolving 200 grms. of good caustic soda in 1250 c.c. of distilled water, adding 2 grms. potassium permanganate, and boiling down until the volume is rather less than 1000 c.c. making up to 1000 c.c. when cold.) The distillate is collected in a flask containing 50 c.c. of water free from ammonia, and 1 c.c. of dilute pure hydrochloric acid, and during the distillation of the first 50 c.c. the delivery tube of the condenser is made to dip into this acid liquid, whilst during the remainder of the distillation the flask is lowered so that the delivery tube is just above the liquid. The distillation is carried on until the whole of the ammonia has passed over, and the contents of the receiver are then 'Nesslerised' in the ordinary way. The most scrupulous care must be exercised to prevent access of ammonia from the air and reagents; a blank experiment should also be made for control.

Determination of dissolved oxygen.—Much importance is, with very little reason, attributed by some analysts to this determination; it can, moreover, be rarely applied, as the samples must be collected with special precautions if the results are to have any value at all. The various processes in use have been examined by Kisch (Chem. Soc. Abstr. 1892, 98). *Reichardt's* method (Zeitsch. anal. Chem. 1872, 11, 271), as modified by Preusse and Tiemann (Ber. 1879, 12, 1768; Tiemann-Gärtner's *Untersuch. d. Wassers*, 278), consists in boiling a measured volume of water, and collecting the gases over a hot solution of caustic potash, the oxygen being then estimated either by explosion with hydrogen, or by absorption with potassium pyrogallate. In *Mohr's* method (*Mohr's Titrimethoden*) the sample is mixed with an acid solution of ferrous sulphate of known strength, then with caustic soda to throw down ferrous hydroxide, and after remaining for a few hours (air, of course, being rigidly excluded), the precipitate is redissolved in sulphuric acid, and the remaining ferrous sulphate titrated with permanganate. In the *Schützenberger-Riesel* process (Bull. Soc. chim. 1873, [ii.] 19, 152; 20, 145; Tiemann-Gärtner's *Untersuch. d. Wassers*, 277, 288; Catherine Williams and Ramsay, Chem. Soc. Trans. 1886, 760; Bernthsen, Ber. 13, 2277; Roscoe and Lunt, Chem. Soc. Trans. 1889, 552; Dupré, Analyst, 1885, 10, 156) the water is allowed to act on a solution of sodium hydriodide disulphonate, which oxygen converts into the blue compound; a standard solution of sodium hydrosulphite is then run in until the liquid again becomes colourless. In *Winkler's* process (Ber. 21, 2843) the water is mixed with a solution of manganous chloride, and then with potassium iodide and caustic potash; the precipitated manganous hydroxide absorbs the oxygen, passing into a higher state of oxidation. On adding hydrochloric acid the higher oxide of manganese gives rise to the liberation of an equivalent quantity of iodine, the amount of which is determined by titration with sodium thiosulphate. According to Kisch (*loc. cit.*), the results by the Reichardt-Preusse-Tiemann method are decidedly lower than those obtained by the Winkler process, which is in harmony

with the experience of the writer. The results by *Mohr's* and *Schützenberger's* methods accord very well with those of *Winkler*; but *Winkler's* appears, on the whole, to be the most trustworthy, and the easiest to carry out. A modification of *Winkler's* method has been made by *Rideal* and *Stewart* (Analyst, 1901, 26, 141), and a more recent one reducing it to a colorimetric process by *Rideal* and *Burgess* (*ibid.* 1909, 34, 193).

A full description and discussion of the several methods will be found in *Sutton's Volumetric Analysis*.

The determination of dissolved oxygen has, in recent years, been much practised in connection with the rate at which dissolved oxygen is absorbed by sewage and effluents from sewage works. This matter is of importance as affording a measure of the readiness with which such liquids will remove the dissolved oxygen from a stream into which they are discharged. For *Scudder's* method, see *Fowler's Sewage Works Analyses*, or *Sutton's Volumetric Analysis*.

Determination of carbon dioxide.—(1) The total carbonic acid is determined by completely precipitating as calcium carbonate with an excess of calcium hydroxide (a sufficient quantity of calcium chloride being added to decompose alkaline carbonates), then filtering off the precipitate, and determining the carbon dioxide in it in the usual way (Fresenius, Quant. An.; Tiemann-Gärtner, *Die Untersuch. d. Wassers*, 213). If the water is saturated with carbon dioxide under pressure, the above method must be preceded by *Rochleder's* process for estimating the gas which escapes on reducing the pressure to that of the atmosphere.

(2) The free and semi-combined carbon dioxide is determined by *Pettenkofer's* method, in which the water is treated with an excess of standard calcium hydroxide solution, and, after the precipitate has separated in a crystalline form, the clear liquid is decanted off, and the excess of lime ascertained in an aliquot part by titration with standard dilute oxalic acid, using phenolphthalein as indicator. If the water contains alkaline carbonates, sufficient neutral calcium chloride solution must be added to decompose them, whilst if there is a considerable proportion of magnesia salts, some ammonium chloride must also be added.

If the carbonic acid thus determined is subtracted from the total obtained according to (1), then the difference represents the combined carbonic acid. To this combined carbonic acid there corresponds, of course, an equal quantity of semi-combined, so that only an excess over and above this can be regarded as free carbonic acid. It must, however, be pointed out that the determination of total carbonic acid generally yields results which are below the truth by 1-1.5 units in 100,000 parts, in consequence of the solubility of normal calcium carbonate itself (v. Walker and Kay, J. Soc. Chem. Ind. 1912, 31, 1013).

Determination of sulphuretted hydrogen.—Colorimetrically with a solution of sodium nitroprusside, using for comparison a standard solution of sulphuretted hydrogen. The latter is standardised by taking a measured volume and adding an excess of decinormal sodium arsenite; shake well, and then acidify with hydrochloric acid. After the arsenious sulphide has com-

pletely subalbed, dilute to 300 c.c., and filter through dry paper. Take 100 c.c. of the filtrate, remove acidity by means of solid sodium carbonate, add a drop of starch solution, and then run in decinormal iodine until a blue colour is obtained. This method may, of course, also be employed for the determination of the sulphuretted hydrogen in the water itself if present in sufficient quantity.

In using the colorimetric method, 300 c.c. of the water are treated with 5 c.c. sodium carbonate and 3 c.c. sodium hydroxide; allow the precipitate to subside for 1-2 hours, then decant or filter. To 250 c.c. of the filtrate in a colourless cylinder add 1 c.c. of sodium nitroprusside solution (4 grms. per litre), and for comparison take 245 c.c. distilled water, to which add 2 c.c. sodium hydroxide and as much of the standard solution of sulphuretted hydrogen as is required to produce precisely the same tint as is obtained with the water above. In this manner 0.1 part H_2S per 100,000 can be determined (Tiemann-Gärtner, Untersuch. d. Wassers, 232).

Sulphuretted hydrogen may also be accurately determined by means of centinormal iodine solution. 10 c.c. or other suitable volume of the latter are placed in a 500 c.c. flask, and the water added until the colour completely disappears; 5 c.c. of starch solution are then added, and centinormal iodine is run in until a blue colour is obtained, pure distilled water being added up to the 500 c.c. mark from a burette. On subtracting the sum of the volumes of iodine, starch solution, and distilled water added from 500 c.c., the volume of water which reacted with the iodine solution employed is ascertained. A correction should be made for the volume of iodine solution required to produce a blue colour.

BACTERIOLOGY OF WATER.

The great progress during the past half century made in our knowledge of infectious diseases and of the processes dependent on bacterial life, has necessitated that the subject of water supply should be considered from a bacteriological, as well as a chemical, point of view.

It had even previously been recognised that in making determinations of organic matter, ammonia, nitrates, &c., with a view to ascertaining the fitness or otherwise of water for drinking purposes, the concomitants of the living poisons of zymotic disease and not the morbid matters themselves, which were still more or less hypothetical entities, were being tested for, and that the living poisons themselves must be explored by biological, and not by purely chemical, methods.

Liquid and solid media.

The classical investigations on bacteria by Pasteur, Tyndall, Lister, Nägeli, Cohn, Fitz, Schloessing, Muntz, and others prior to 1880 were practically all made with liquid culture media only. Such culture media labour under several serious disadvantages:—

(1) Facility with which they become contaminated with bacteria and other organisms from the air and other surroundings;

(2) The competition which arises between

the different microbes present may lead to the entire suppression of some through the overwhelming multiplication of others;

(3) The great difficulty of obtaining pure cultivations of specific micro-organisms.

The introduction of solid culture media by Koch at the beginning of the 'eighties, in the last century, led to great developments in bacteriology. An immense variety of investigations were now rendered possible which had long been awaiting attack. These new methods of bacteriological study were at once applied to the identification of the specific micro-organisms of numerous diseases, and to the investigation of the bacteria present, in *air, water, soil*, and all our other surroundings.

By means of *gelatin-plate-culture* it became possible to ascertain the number and the nature of most bacteria present in any material. Thus in the case of water the number and nature of the bacteria present in any sample could be determined, and by this means it was possible to ascertain the effect of any treatment or process of purification on the bacteria present in water. Thus it was applied by the writer in 1885 to the study of the removal of bacteria from water by artificial and natural filtration, by *subsidence*, and by *precipitation*.

The results obtained in investigations of this kind led to a great modification of the opinions which had previously been entertained with regard to the value of these processes in removing the zymotic dangers of water. Thus it was found that bacteria could be almost wholly removed from water by the process of sand filtration which had a comparatively insignificant effect on the organic matter and other ingredients discoverable by chemical analysis.

Similarly these methods of bacteriological investigation enabled such processes of water purification to be readily controlled. Thus if the safety of a water-supply depends on the efficiency with which the removal of bacteria by filtration is carried out, it is obvious that this efficiency should be continually controlled by bacteriological examination, so that any defect in the working of the filters may at once be detected and rectified. The systematic control of water-works by bacteriological examination is now being very widely carried on with great benefit to the communities concerned.

With the discovery of the specific bacteria of cholera, of typhoid fever, and of many other diseases, attempts were naturally made to find these specific pathogenic bacteria in contaminated water-supplies. The chance of such discovery by the ordinary method of plate-cultivation is, of course, hopelessly remote, because a single pathogenic organism must almost inevitably be accompanied in water by a host of non-pathogenic individuals, and amongst these multitudes of harmless forms the few harmful ones will under ordinary circumstances be overlooked, whilst, in the small quantities of water operated on, the pathogenic forms may be absent, although present in a larger bulk.

To surmount these difficulties, the natural device was to provide conditions which would be favourable to the particular pathogenic form being sought for and less favourable or even antagonistic to the multitude of non-pathogenic forms with which it would be accompanied.

We may call the provision of such conditions the method of *enrichment or preferential culture*.

Such a method of enrichment was very satisfactorily applied by Koch to the discovery of the *cholera-bacillus* in the water of the Elbe at Hamburg during the epidemic of 1892. If 90 c.c. of the water under examination be incubated for 18 hours at 37° with 10 c.c. of a solution containing peptone 10 p.c., and sodium chloride 10 p.c., cholera bacilli will be found in the thin surface pellicle, and from this cultures are made.

Typhoid fever is, of water-borne diseases, the most important in Western Europe. An enormous amount of labour and ingenuity have been devoted in recent years to the discovery of the bacillus of this disease in water. That the problem is a very difficult one may be gathered from the fact that until recently its detection even in the discharges of typhoid patients was very frequently abortive.

The special difficulty attending the discovery of the typhoid bacillus depends on the circumstance that even in the intestine of the typhoid patient it is enormously outnumbered by other bacteria, and especially by the *Bacillus coli communis*, which, discovered by Escherich in 1886, has in recent years achieved the very greatest celebrity in the bacterial world.

Practically all conditions which are favourable to the typhoid bacillus are equally or even still more favourable to the *B. coli*, and for a long time all methods of favouring the typhoid bacillus at the expense of the *B. coli* proved futile. Much interest was, therefore, excited when in 1903 Roth announced that the *B. coli* was more disadvantageously affected than the typhoid bacillus by solutions of caffeine.

Experiments made by Kloumann¹ in 1904, however, showed that the differential effect on the two bacilli was only very slightly in favour of the typhoid bacillus.

A method of testing for typhoid bacilli in water and other liquids was elaborated by Hoffmann and Ficker in 1904; it was also based on the inhibitory action of caffeine and of crystal-violet on the *B. coli*. The method will be best understood by the following description of the manner in which it was successfully employed by Jaksch and Rau (1904) to detect typhoid bacilli in the drinking water supplied to Prague:—

900 c.c. water from a service tap were added to the Hoffmann and Ficker culture-medium, consisting of 10 grms. nutrose, 5 grms. caffeine, and 0.01 grm. crystal-violet, in 100 c.c. water.

The mixture was then incubated at 37° for 13 hours, when it was to be presumed that any typhoid bacilli originally present would have extensively multiplied. Loopfuls of this large cultivation were then withdrawn and spread on the surface of Drigalski and Conrad's Plates (agar, meat extract, peptone, nutrose, lactose, sodium chloride, crystal violet and litmus), which were then incubated at 37° for 24 hours. On these plates the *B. coli* colonies are red (acid litmus) and non-transparent, whilst those of the typhoid bacillus are blue with a violet-tinge, transparent, resembling dewdrops, and smaller than the *B. coli* colonies. In the Prague experiments these plates gave only a few red

colonies, the majority being blue and transparent. The latter were sub-cultured, and, according to Jaksch and Rau, gave results in the most varied tests (including agglutination, toxicity, and immunisation) which were identical with those obtained with the true typhoid bacillus.

Other solid media which have proved of great value in distinguishing between coli-like and typhoid-like colonies are Loeffler's malachite-green agar, and McConkey's bile-salt-neutral-red agar, both of which will be referred to later.

By far the most extensive, interesting, and systematic search which has ever been made for the typhoid bacillus in natural waters is that carried out by Houston on the waters of the three rivers—Thames, Lea, and New River—from which the greater part of the London water supply is obtained. As this investigation illustrates the most approved methods which are now available to the bacteriologist, it will be considered here in some detail.

Two hundred and ninety-four experiments in 8 series were made with 156 samples of raw river water (52 Thames, 52 Lea, and 52 New River) during the 12 months ended July 31, 1908. The total volume of water dealt with was $294 \times 100 = 29,400$ c.c. The total number of bacteria in this volume of water (as ascertained by gelatin-plate cultivation for 3 days at 20°–22°) was 135,687,500. The total number of colourless (or nearly colourless) colonies sub-cultured from the Drigalski or similar plates was 7329. These 7329 selected colonies form but a small fraction of the millions of bacteria which were excluded owing to the temperature of incubation, the composition of the media employed, and the fact of their appearing on the plate-cultures as coloured colonies.

The following tabular summary indicates the method adopted in this exhaustive investigation:—

Direct Plating on Solid Media.

Series I. 100 c.c. of the sample of water were centrifuged and the resulting deposit spread over a number of plates consisting of malachite-green (1 in 5000), saccharose, dulcine, salicin, neutral-red, bile-salt, peptone, lactose, agar. The plates were incubated at 40°–42° for 24 hours, and the colourless colonies sub-cultured into special media, as described in the next table.

Series II. Same as Series I, but the proportion of malachite-green was 1 in 10,000.

Series III. Same as Series I, but the medium used in the plates contained no malachite-green.

Series IV. Same as Series I, but the proportion of malachite-green was 1 in 20,000, 1 in 40,000, and 1 in 80,000.

Primary Liquid Cultures followed by Plating on Solid Media.

Series A. 100 c.c. of the sample of water were added to bile-salt-glucose-peptone medium containing malachite-green in proportion of 1 in 1000, 1 in 2000, 1 in 4000. This liquid was incubated at 40°–42° for 24 hours, and then plated on the same medium as was employed in Series I, 10 colourless colonies were in each case sub-cultured and tested as described.

Series B. Same as Series A, but malachite-green in the liquid medium was in proportion

¹ Kloumann, Centralbl. f. Bakteriologie, 1904, 36, 312.

of 1 in 8000, 1 in 16,000, 1 in 32,000. Subsequently plated on same medium as that used in Series II.

Series C. Same as Series A, but the liquid culture medium consisted of meat-broth only without malachite-green or any other additions. Subsequently plated on same medium as that used in Series I.

Series D. Same as Series C, but instead of cultivating 100 c.c. of water in one

portion, 10 cultures of 10 c.c. each were made.

The following table shows the behaviour of 32 strains of the typhoid bacillus, on the one hand, and of the 7329 suspicious colonies isolated from the raw waters, on the other. It will be seen that not one out of all these 7329 different microbes, although suspicious in certain features, gave reactions agreeing in their entirety with those of the typhoid bacillus.

VERIFICATION TESTS FOR TYPHOID BACILLUS.

	Test 1	Test 2	Test 3	Test 4	Test 5	Test 6
Description of microbe.	Proskauer's and Capaldi's No. 2 medium ¹ (with inner tube).	Lactose-saccharose dulcitate-salicin-medium (with inner tube).	Proskauer's and Capaldi's No. 1 medium ² modified (with inner tube).	Glucose-neutral red broth cultures (with inner tube).	Peptone-water medium.	Gelatin sugar media:—galactose, glucose, levulose, maltose, and mannite respectively.
RESULTS CHARACTERISTIC OF TYPHOID BACILLUS.						
32 strains of typhoid bacillus from a number of different laboratories.	Acid, no gas	No visible change (No acid, no gas.)	No visible change. (No acid, no gas.)	Purplish tint. (No gas, no fluorescence.)	No indole	Acid, but no gas with all five sugars. No liquefaction.
RESULTS WHICH EXCLUDE, AS NOT TYPHOID BACILLUS, THE SUSPECTED MICROBES.						
7329 colourless (or nearly colourless) colonies, sub-cultured.	No acid, or acid and gas	Acid or gas formation.	Acid or gas formation, or decided growth.	Gas or fluorescence. (Absence of purplish tint.)	Indole	Gas formation in one or all of the sugar media. (Liquefaction.)

¹ Solution of peptone and mannite.

² Solution of asparagine, mannite, glucose, galactose, levulose, maltose, magnesium sulphate, sodium chloride, calcium chloride, potassium hydrogen phosphate, and litmus.

From the very nature of this investigation—the search for a specific microbe in a natural water which at some period in its history is practically certain to have received this microbe in comparatively small numbers—it is impossible to make it really exhaustive. Houston has, however, amplified his previous investigation in a very suggestive manner. Realising that the objection might be raised that the method adopted may not be capable of detecting a very small number of typhoid bacilli in the presence of a very large number of other microbes, he devised a mode of procedure which enabled him to affirm that in each particular sample of water examined there were not more than a certain definite number of typhoid bacilli in a given volume. The method adopted was this:—

Each sample of raw river water was divided into two equal portions of 500 c.c. (A and B). The A sample was inoculated with a very small number of typhoid bacilli. The B sample was not so infected, and was, therefore, normal raw river water. The subsequent procedure was exactly the same in each case, both samples A and B being treated exactly alike. The 500 c.c. of water were centrifuged and the resulting deposit spread over 16 plates prepared with solid medium of the following composition:

Agar, 2 grms.; peptone, 2 grms.; bile-salt, 0.5 gm.; lactose, saccharose, adenite, raffinose,

and salicin, each 0.2 grm., made up with water to 100 c.c. and tinted with 0.4 c.c. of a 1 p.c. solution of neutral red. In some of the experiments malachite-green was added to the above, in the proportion of either 1 to 10,000, or 1 to 5000 of the medium.

Of the 24 experiments, 14 were carried out with raw Lea, and 10 with raw Thames, water. These waters contained on an average 62,688 bacteria per 1 c.c. (gelatin at 20°-22°, 3 days' incubation). The worst sample contained 760,000 and the best sample 1200 bacteria per 1 c.c. Thus in the 12 litres (500 c.c. × 24) of raw water (B samples) examined for typhoid bacilli there were 752,256,000 bacteria present.

The total number of colonies selected for study was 5451 from the infected A samples, and the same number (5451) from the non-infected B samples. The average number of typhoid bacilli artificially added to the A samples was 2.242 per 1 c.c. or 1121 per 500 c.c. The average number of typhoid bacilli isolated from the A samples was 14.54 per 500 c.c. of sample. It may be argued fairly, therefore, that if only $\frac{1}{14.54}$ of the above number of typhoid bacilli had been present in the infected sample this microbe would still have been detected by the method of investigation adopted; but $\frac{1}{14.54} \times$

2.242=0.154 typhoid bacillus per 1 c.c., or 1 typhoid bacillus in 6.5 c.c. would have been detected.

From the uninfected B samples, out of the 5451 colonies selected for special study, one, and only one, consisted of bacteria which resembled the typhoid bacillus very closely.

It will be instructive to record the observations which were made on submitting this typhoid-like microbe (Lee W. 694? *B. typhosus*, Houston) to the several tests used in the diagnosis of typhoid bacilli.

Characterisation of typhoid-like bacillus from raw river water (Lee W. 694? B. typhosus, Houston).

Morphology.—A motile multiflagellate bacillus. The rods seemed shorter than in most strains of *B. typhosus*.

Gelatin and agar slope-cultures.—Possibly the growth was slightly less filmy in character than that of the true *B. typhosus*.

Glucose-bile-salt agar-slope (neutral red).—The streak somewhat brighter and cleaner red than in most strains of *B. typhosus*.

Lactose-bile-salt agar-slope (neutral red).—Colourless streak.

Potato.—No visible growth (5 days at 37°).

Nitrate-broth.—Reduces nitrates to nitrites.

Peptone-water at 55°F.—No visible growth after 5 days; on transferring tube to incubator at 37°C. growth occurred within 24 hours.

Indole test.—No indole formation (5 days at 37°).

Liquid peptone (1 p.c.) media containing separately 1 p.c. of the substances stated and tinted with litmus. Sorbite and inosite are only used in 0.2 p.c. solution. Acid but no gas in sorbite, mannite, glucose, levulose, galactose, and maltose respectively (2 days at 37°). No change in inulin, inosite, saccharose, salicin, adonite, lactose, dulcete, and raffinose respectively (5 days at 37°).

Gelatin glucose medium tinted with litmus.—Acid but no gas formation.

Voges and Proskauer's reaction.—Negative result, 5 days.

Gelatin.—No liquefaction after one month at 20°.

Litmus milk.—Slight acid but no coagulation (5 days at 37°).

Glucose-neutral-red-broth cultures.—No gas, no fluorescence characteristic purplish tint.

Lactose-saccharose-dulcete-sulcin-peptone medium tinted with litmus.—No change (2 days at 37°).

Proskauer and Capaldi's Medium No. 1 (modified).—No change (2 days at 37°).

Proskauer and Capaldi's Medium No. 2.—Acid but no gas.

Agglutination experiments and tests for pathogenicity.

Anti-typhoid serum.—Microscopically, 1:200 almost instantaneous clumping, 1:800 very fair clumping, 1:2000 little or none. *B. typhosus* tested with the same serum gave very similar results but appeared to be clumped slightly more rapidly and in slightly higher dilutions. The difference, however, if any, was not well marked.

• *Serum of an animal immunised with the suspected microbe (Lee W. 694? B. typhosus, Houston).*—Microscopically, 1:200 very rapid and satisfactory clumping; 1:2000 good, but not quite complete clumping within half an hour.

B. typhosus tested with the same serum gave very similar results, but was perhaps clumped a little more slowly and in slightly lower dilutions. The difference, however, if any, was not well marked. Microscopically, the titre limit was about 1:8000 (18 hours) and was practically the same for both microbes.

Pathogenicity.—2 c.c. of a broth-culture injected subcutaneously into a guinea-pig produced a swelling and illness with recovery. A guinea-pig intraperitoneally inoculated with 5 c.c. of a broth-culture died in less than 24 hours.

On the results of this laborious investigation, which had extended over more than two years, and which had been conducted with the most meticulous care and regardless of time and money, Dr. Houston very cautiously remarks: 'If this microbe had been isolated from a case of typhoid fever (or from a suspected case) I do not think any serious hesitation would have been felt in describing it as *B. typhosus*.'

It would be impossible to produce more eloquent testimony than the above as to the enormous and almost prohibitive trouble which a systematic and conscientious search for the typhoid bacillus in natural water entails.

Comparative unimportance of searching for the typhoid bacillus in water.—The almost hopeless nature of the search for the typhoid bacillus in natural waters is of the less importance as the anxiety to detect this microbe in water is, for the most part, based upon an entire misconception of the objects of water examination. The object of a water examination is, in general, not to determine whether the particular sample of water contains typhoid bacilli and is, therefore, capable of carrying typhoid to the consumer, but to discover whether the water is likely at any time to contain such infective material.

Now any water which receives sewage matters must be regarded as a possible carrier of typhoid infection, for at any time these sewage matters may be derived from persons suffering from typhoid. Thus any sewage-contaminated water is a potential carrier of typhoid unless it has been subjected to conditions which would ensure the removal of the possibly present typhoid bacillus. Thus the all-important thing is to ascertain whether a given water has been contaminated with sewage, in what proportion such contamination has taken place, and whether the water since such contamination has been submitted to conditions which would remove or destroy typhoid bacilli should they have gained access with the sewage matters.

Firstly, as regards the detection of sewage contamination. Excremental contamination, if sufficient in amount, can be revealed with more or less certainty by chemical analysis, which can indeed even distinguish between whether such pollution is recent or remote in point of time, but in order to ascertain the fate of bacteria gaining access to water resources must be had to biological methods. If there were bacteria absolutely characteristic of sewage, the determination of their presence would be sufficient to

prove the danger of a water. Unfortunately we do not know of any bacteria which satisfy the condition of being *absolutely* characteristic of sewage, so we must be satisfied with a second best qualification for diagnostic purposes by those which are *very* characteristic of sewage.

The microbe which is most characteristic of the intestinal discharges of man and the higher animals is, as its name implies, the *B. coli communis*, and a great amount of time and ingenuity has been devoted to its accurate and expeditious discovery in water and other materials.

In identifying a particular organism, whether plant or animal, we depend on recognising in the individual a certain group of specific characters which are more or less arbitrary. The botanist at first tried to classify and distinguish bacteria by external appearances alone; he measured the length and breadth of these minute organisms; he counted the number of flagella with which some of them are provided; he was very careful to observe whether they were square or round at the ends, and so forth.

These morphological characters have, however, long been recognised as inadequate for purposes of identification, since organisms exhibiting the closest morphological similarity have been found to differ enormously in other respects.

After the introduction of Koch's methods much attention was directed to the macroscopic appearances to which the organisms give rise when grown on a variety of solid media, by which means microscopically similar bacteria can often be differentiated.

Some 35 years ago the writer commenced distinguishing bacteria, which were similar in form and in cultural appearances, by differences in the chemical changes which they could bring about in certain media. Thus he found that the capacity to reduce nitrates to nitrites was in some cases a valuable means of distinguishing between otherwise similar bacteria. This reduction of nitrates has been extensively used for diagnostic purposes, more especially by American bacteriologists. Somewhat later he devoted much attention to the fermentation of carbohydrates, polyhydric alcohols, and hydroxy-acids, by means of pure cultivations of micro-organisms, and showed how capricious is the power possessed by different bacteria in this respect. Thus perhaps one microbe will ferment glucose, mannite, and glycerol, but not dulcitol or glyceric acid, another will ferment glucose, mannite, and dulcitol, &c.

There are, however, many bacteria which more or less simulate the characters of the typhoid bacillus on the one hand, and of the *B. coli* on the other; such forms exhibit almost every degree of approximation to one or other of these two types, from which they can only be distinguished by applying a number of tests. Such forms are designated as *atypical*, and what their relationship to the typical typhoid and coli bacteria may be is a matter of uncertainty. Possibly in some cases they may have been typical forms originally, but under the particular conditions to which they have been submitted they have lost some of their characters. Thus it is often found that the *B. coli*, on prolonged

artificial culture, may lose either or both its indole-producing and milk-curdling properties.

This mode of differentiating between otherwise very similar forms of bacteria has been greatly extended within recent years. In the following table the classification of the Typhoid-coli group of bacteria into seven sub-groups has been attempted:—

TYPHOID-COLI GROUP.

Sub-groups	Glucose	Acid gas	Lactose	Acid gas	Dulcitol	Acid gas	Saccharose	Acid gas
I.								
<i>B. Typhosus</i> :	+	-	-	-	-	-	-	-
<i>B. dysenteriae</i> :	+	-	-	-	-	-	-	-
<i>B. faecalis-alcaligenes</i> :	-	-	-	-	-	-	-	-
II.								
<i>B. enteritidis</i> (Gaertner) :	+	+	-	-	+	+	-	-
<i>B. paratyph</i> :	+	+	-	-	+	+	-	-
<i>B. paracoli</i> :	+	+	-	-	+	+	-	-
III.								
Bacillus from urine :	+	+	-	-	-	-	+	+
IV.								
<i>B. acidilactici</i> (Hueppe) :	+	+	+	+	-	-	-	-
V.								
<i>B. coli</i> (Escherich) :	+	+	+	+	+	+	-	-
VI.								
<i>B. pneumoniae</i> (Friedländer) :	+	+	+	+	+	+	+	+
VII.								
<i>B. capsulatus</i> (Pfeiffer) :	+	+	+	+	-	-	+	+
<i>B. lactis aerogenes</i> (Escherich) :	+	+	+	+	-	-	+	+
<i>B. cloacae</i> (Jordan) :	+	+	+	+	-	-	+	+

It is obvious that by increasing the number of biochemical tests many further variations of a given type of organism may be discovered, and, for the purpose of more precisely defining a particular microbe, bacteriologists have introduced biochemical tests involving the use of a variety of organic compounds—more especially carbohydrates, polyhydric alcohols, and glucosides. These tests generally consist in ascertaining whether an organism under investigation gives rise to acid or gas, or both, or neither, in a suitable nutritive medium containing one of these substances. The following list of substances employed in this manner will give some idea of the degree to which these biochemical tests have been complicated in recent years: adonite, asparagine, dextrin, dulcitol, erythrite, galactose, glucose, glycerol, glycol, isodulcitol, lactose, levulose, maltose, mannite, mannose, nutrose, raffinose, sucrose, salicin, sorbite, and starch. The above list by no means exhausts the number of organic substances which are acted on by bacteria, and by means of which, therefore, differences can be established.

Although such tests are extremely useful for the more precise definition of particular micro-organisms, they must be employed with discrimination, for as the writer long ago pointed out, these fermentations, as well as other characters of bacteria, are liable to be lost through conditions of environment, and he has also shown how in some cases they may be

restored by resorting to particular methods of culture and training.

It is obvious that it would be impracticable to resort to such numerous tests in the ordinary bacteriological examination of water in which we are concerned with the detection of sewage or excremental contamination, unless some very great advantage should result from such multiplication of tests, and this is not the case at present.

Quantitative determination of B. coli in water.—If we regard the *B. coli* provisionally as the best indicator of contamination with the living bacteria of animal refuse, we shall obviously view its presence with the more suspicion the larger the numbers in which it is discovered in a given volume of water.

The numerous methods which have from time to time been devised for detecting *B. coli* will be passed over, and only the one which in this country at any rate has superseded all others will be described.

An important departure in practical bacteriology was the introduction by McConkey and Hill ('Bile-salt broth. A simple test for faecal contamination.' Thompson-Yates Laboratories Report, 1901, 4, [i.] 151) of a medium for the preferential culture of the *B. coli* and allied microbes from mixtures of micro-organisms. The essential ingredients of this medium are sodium taurocholate (bile-salt) 5 grms., glucose 5 grms., peptone 20 grms., water (tinted with litmus) 1000 c.c. Incubated in this liquid at 37°-42° bacteria of the *B. coli* group give acid and gas in 48 hours. Some bacteriologists use lactose instead of glucose, thus restricting the gas production to *B. coli* and its still closer allies. With this liquid medium in Durham fermentation-tubes cultivations of the water are made in the following quantities: 100, 10, 1, 0.1, 0.01, 0.001, 0.0001, 0.00001 c.c. The concentration of the medium should in all cases be approximately the same as that given above. In order, therefore, that the volumes of liquid incubated may not be inconveniently large, the 10 and 100 c.c. of water are introduced into correspondingly stronger McConkey media.

A positive reaction, i.e. the production of acid and gas, in any of these culture-tubes signifies that at least one coli-like microbe must have been introduced with the portion of water added. Thus, if acid and gas had been obtained, in a particular case, with all the tubes from 100 to 0.1 c.c., this would mean the 'presumptive' presence of at least one *B. coli* in 0.1 c.c., and its absence in 0.01 c.c. and smaller volumes of water.¹

¹ There is one element of uncertainty connected with such tests made in liquid media which appears to be tacitly ignored by all bacteriologists who make use of them, and that is that the particular microbe sought for may in the process of cultivation in the liquid medium become hopelessly outnumbered or even suppressed by the much more abundant proliferation of some other microbe or microbes present in the mixture.

Thus the McConkey medium may be taken as a priori favourable for the proliferation of bacteria of the *B. coli* type, but the water-bacteriologist is in general restricting his search to those bacteria which are sufficiently like typical *B. coli* as to produce acid and gas in the medium. Is it not possible that the bacteria capable of producing both acid and gas may be so greatly outnumbered by microbes not giving this reaction that the more typical *B. coli* forms may be so much kept in abeyance that no acid and gas reaction is obtained? Under these circumstances he would

* In order to ascertain whether the 'presumptive' *B. coli* is typical or not, the tube containing the smallest portion of water which has given rise to acid and gas in the McConkey medium is plated on a solid medium of the following composition: Agar 20 grms., peptone 20 grms., sodium taurocholate (bile-salt) 5 grms., lactose 10 grms., neutral red (1 p.c. solution) 4 c.c., made up to 1000 c.c. with water. After 12 hours' incubation at 37°, the colonies will be distinctly visible, and those which are most likely to be *B. coli* will have a strong red colour owing to the acid produced by this microbe in the medium. Five of the most typical red colonies are separately inoculated into 5 glucose-litmus broth tubes, which are then incubated at 37°. Any of these 5 tubes which develop acid and gas are then each further inoculated into tubes of the following media which are then incubated at 37°:—

(a) Neutral red broth to be examined for fluorescence.

(b) Litmus lactose-broth to be examined for acid and gas.

(c) Ordinary broth to be examined for indole.

(d) Litmus-milk to be examined for acid and coagulation.

(e) Gelatin to be examined for non-liquefaction.

The above glucose-tubes from which these inoculations have been made are also microscopically examined to see whether the microbe possesses the characteristic form and motility of the *B. coli*.

A microbe fulfilling these conditions has been designated by Houston as 'Flaginac' *B. coli*, from Fl—fluorescence in neutral-red broth, ag=acid and gas in lactose, in=indol in peptone broth, ac=acid and coagulation in litmus-milk.

The typical *B. coli* from human faeces gives these reactions, but, of course, it is possible to further differentiate between coli-bacteria by additional tests, such as fermentation of sucrose, dulcitol, mannitol, &c., but at present there would not appear to be any advantage in such multiplication of tests in the ordinary examination of water.

The following table summarises an interesting investigation made by Houston on the proportion of 'Flaginac' *B. coli* found amongst the coli-like microbes obtained from different sources:—

FLAGINAC *B. COLI*.

Source	Number of specimens of <i>B. coli</i> or coli-like microbes on which flaginac percentage is based	P.c. of <i>B. coli</i>
Milk	243	61
Human faeces	101	85
Sewage	several hundreds	65-85
Oysters	464	43
Estuarial waters	183	68
Water-crees	81	40
Washings of crees	52	52
Water in which crees was grown	42	76
London filtered water	232	31

obviously draw the conclusion, and quite erroneously, that acid and gas producing microbes (and, therefore, *B. coli* amongst them) were absent. This is a matter which requires much further investigation before the conclusions as to absence of *B. coli* generally drawn can be justified.

In the following table are recorded the results of some very suggestive pioneering experiments made by McConkey (1905), undertaken with the object of ascertaining whether there is any marked difference in the types of *B. coli* found in the excreta of man and some of the common domestic animals respectively. Should it be possible to establish such a difference, an important means of distinguishing between human and animal excrementitious contamination of water would be obtained.

Such an investigation would have to be enormously extended before results capable of being used for diagnostic purposes could be obtained.

An attack on the same important problem was also made by Dr. Wm. G. Savage (1904-5) in an extremely laborious investigation, which he has summarised in the foregoing table.

The absence of streptococci in the faeces of the pig is extremely remarkable.

It is convenient to classify waters tentatively

B. COLI FROM HUMAN AND ANIMAL EXCRETA (McCONKEY).

Group	Fermentation of		Number of lactose-fermenting Coli-form microbes isolated and experimented with			Results in percentages		
	Saccharose	Dulcité	Human	Animal ¹	Total	Human	Animal	Average
I.	—	—	83	37	120	34	15	25

Pig No. 2	10 to 100 millions	Absent	10,000 to 100,000
Pig No. 3	70 millions	Absent	1000 to 10,000
Sheep No. 1	10 to 100 millions	1 to 10 millions	10 to 100
Sheep No. 2	10 to 100 millions	10 to 100 millions	10 to 100

according to the results of the examination for *B. coli*, thus:—

CLASSIFICATION OF WATER BY *B. COLI* TEST.
(1 c.c. of sewage is assumed to contain 100,000 *B. coli*.)

Class	Volume of water examined	<i>B. coli</i> per 1 c.c.	Pollution in sewage
I	a.c.	0	per cent.
II	—in 100	0	—
III	+in 100	0.01	0.00001
IV	+in 10	0.1	0.0001
V	+in 1	1	0.001
VI	+in 0.1	10	0.01
VII	+in 0.01	100	0.1
VIII	+in 0.001	1,000	1
IX	+in 0.0001	10,000	10
		100,000	100 (pure sewage)

This classification must not, however, be interpreted too rigidly, as it is based on the assumption that *B. coli* is always derived from faeces and that this microbe is incapable of multiplication under any circumstances after incorporation in what is known as 'sewage.'

In the two following tables are recorded the results of the ordinary bacteriological examination of a number of typical waters. The tables sufficiently explain themselves.

Storage of water.—In 1886 (Water Purification, its Biological and Chemical Basis, Trans. Inst. Civil Engineers, 1886) the writer pointed out the great importance from a theoretical point of view of storage for the purification of surface waters. In 1892, again, he investigated the influence of storage on the bacteriological purity of the river waters abstracted for the supply of London, and showed that there is a most striking reduction in the number of

suspended micro-organisms during storage in large reservoirs.¹

¹ Appendixes to Minutes of Evidence, Roy. Commission on Metropolitan Water Supply, 1893, 469-475. See also "Micro-organisms in Water," P. Frankland and G. C. Frankland, London, 1894, pp. 99, 126, 131-142, 154.

The great importance of storage from the hygienic point of view was further manifest from the experiments made on the fate of pathogenic bacteria introduced into natural waters, and which showed that the duration of life of these bacteria under such conditions is generally very short.

In 1891-4 the writer had the opportunity of greatly extending his observations on this subject, as he was requested by a Committee of the Royal Society to make, in conjunction with the late Professor Marshall Ward, F.R.S., a special inquiry into the vitality of pathogenic bacteria in potable waters (see Proc. Roy. Soc.). The experiments were restricted to the study of the behaviour of the anthrax bacillus (and its spores), the typhoid bacillus, and the *B. coli communis*, and the potable waters employed were those of the Thames, Loch Katrine, and deep-well water from the chalk, these being fairly typical of the different kinds of water used for drinking purposes in this country. Experiments were made with these waters in their natural, and also in a sterilised, condition.

The results obtained may be summarised as follows:—

(1) Unsterilised water infected with anthrax bacilli containing spores was still virulent after being kept for 7 months.

(2) Anthrax bacilli taken directly from an animal dead of anthrax, and, therefore, free from spores, died rapidly (mostly in 5 days) when introduced into unsterilised water kept at low temperatures (5° and 13° in these experiments), but when introduced into the same waters and kept at 19°, the bacilli formed spores, and the latter were still present in enormous numbers even 42 days later, and doubtless for a much longer period still. This remarkable difference in behaviour is accounted for by the fact, previously discovered by Koch, that anthrax bacilli do not form spores below 16°.

The following results were obtained by introducing typhoid bacilli from one and the same cultivation and in the same numbers into each of the waters at one and the same time:—

Unsterilised water	Life of typhoid bacilli
Thames water (Oct. 19, 1893) 9°-12°	Between 0 and 13 days
Loch Katrine water (Oct. 19, 1893) 9°-12°	" 19 " 33 "
Deep well water (Oct. 19, 1893) 9°-12°	" 33 " 39 "
In two other separate experi- ments with unsterilised Thames water (May 11, 1893)	" 25 " 34 "
and (Jan. 16, 1894) . . .	" 20 " 27 "

In all these experiments only 1 c.c. of water was examined for typhoid bacilli, and the method of search, the best known at the time, was that due to Parietti, in which the water is cultivated in a phenol-broth medium at 37°, which on becoming turbid is submitted to plate-cultivation, the colonies obtained being then examined in detail for identification.

It is particularly interesting to compare with the above results those obtained by Houston in a perfectly similar inquiry and making use of all the most modern developments of bacteriological technique. Dr. Houston made 18 experiments on raw Thames, Lea, and New River waters, infecting them with typhoid bacilli (the number added being in all but three experiments very large, see table below). The presence of the bacillus was tested for at weekly intervals in 1 c.c. by means of a medium con-

taining *Agar-bile-salt-dulcitol-lactose-saccharose-salicin-peptone-neutral-red-malachite-green*, and which is specially designed to favour the growth of this microbe whilst repressing that of most others. The results may be summarised in the following statement:—

In 3 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 1 week.

In 10 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 3 weeks.

In 16 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 4 weeks.

In 18 experiments the typhoid bacillus was undiscoverable in 1 c.c. in 5 weeks.

Thus, notwithstanding the great advances made in the technique of testing for the typhoid bacillus, the results obtained by Houston are essentially similar to those obtained by the writer 15 years previously. Houston has, however, extended the investigation in an interesting manner by ascertaining the length of time required before even 100 c.c. of the infected water gave a negative result on being tested by the most modern methods for the presence of the typhoid bacillus. The whole of Houston's investigations (both for 1 c.c. and for 100 c.c. of water tested) is instructively summarised in the table on p. 414.

This table shows, on the one hand, that whilst in each case nearly all the typhoid bacilli are destroyed by a single week's residence in these raw river waters, a few individuals persist for a much longer period of time. This illustrates in a very interesting and instructive manner a principle emphasised by the writer some 16 years before, 'that one of the factors determining the longevity of pathogenic bacteria placed in water, or for the matter of that placed in any unfavourable surroundings, is the absolute number in which they are present. In other words, amongst, for instance, 1000 bacteria taken from a given source there may be some individuals which will resist a particular reverse influence, whilst amongst 10 bacteria taken from the same source there may be some capable of resisting the adverse influence in question' (P. F. Frankland, Proc. Roy. Soc. 1894, 56, 486).

Before leaving the subject of the behaviour of the typhoid bacillus in water, mention must be made of some extremely interesting and ingenious experiments by the American bacteriologists, Jordan, Russel, and Zeit, in 1903. These investigators endeavoured to imitate natural conditions more closely than has been done in any other experiments by placing the typhoid-infected waters in permeable sacs made of celloidin and parchment, and then by submerging these in river, canal, or lake water, their contents were exposed to the influence of the dialysable substances present in the water under natural conditions.

Zeit experimented with Lake Michigan water and Chicago river water, the natural bacterial content of which varies between 68 and 2000 microbes per 1 c.c. in the case of the Lake, and between 80,000 and 1,500,000 microbes per 1 c.c. in that of the river water. Parallel experiments were made with infected water placed in ordinary bottles and in permeable sacs respectively. The typhoid bacilli introduced varied between 500 and 2,000,000 per 1 c.c. The destruction of the typhoid bacillus

was taken as complete when negative results were obtained on cultivating 5 c.c. of the water, the death of the typhoid bacillus being generally confirmed by the subsequent cultivation, a few days later, of much larger volumes, sometimes as much as 800 c.c. of the water. Nine experiments were made with the Michigan Lake water, the typhoid bacillus being never found after the eighth day. Five experiments were made with the Chicago River water, the typhoid bacillus being never found after the third day.

Jordan experimented with the water of the Chicago Drainage Canal, which usually contains from 100,000 to 400,000 bacteria per 1 c.c. This water was infected with from 180 to 857,000 typhoid bacilli per 1 c.c. In these experiments, however, the maximum volume

submitted to cultivation appears to have been only 1 c.c., and from negative results with even smaller volumes the death of the typhoid bacillus seems to have been concluded. Twenty-eight experiments were made in permeable sacs submerged in the canal, the typhoid bacillus being never detected after the second day, excepting in one experiment in which it was still found on the tenth day.

Russel's experiments were made with the Illinois River water, which contains from 1800 to 4000 bacteria per 1 c.c. This water was infected with 540 to 20,000 typhoid bacilli per 1 c.c. However, in these experiments, again, 1 c.c. appears to have been the maximum volume of water cultivated for the detection of the typhoid bacillus. Fourteen experiments

were made in permeable sacs submerged in the Illinois River, the typhoid bacillus being never found after the third day, excepting in one case in which it was detected on the ninth day.

More recently, again, Houston has taken typhoid bacilli not from cultivations but from the human subject and introduced them into raw Thames water. He found that such bacilli perished very rapidly—much more quickly in fact than had been his experience with cultivated strains of the microbe.

The uncultivated typhoid bacteria were obtained from the urine of a 'typhoid carrier,' and on Aug. 9, 1910, the centrifuged deposit (3.5 c.c.) from 389 c.c. of urine was added to 8000 c.c. of raw Thames water; the number of typhoid bacilli was determined as follows:—

At time of mixture, 770,000 typhoid bacilli per 1 c.c. of river water.

After 1 week, 4 typhoid bacilli per 1 c.c. of river water.

After 2 weeks, 0 typhoid bacilli in 100 c.c.

On the 24th day from the commencement of the experiment half-a-pint (about 284 c.c.) of the infected water was drunk, this quantity of water having originally contained 218,680,000 typhoid bacilli. Similar amounts were drunk with impunity on the 25th, 26th, 27th, and 28th days after the beginning of the experiment.

On Aug. 19, 1910, the experiment was repeated with a fresh sample of urine, the number of typhoid bacilli per 1 c.c. of river-water being 1650. A week later no typhoid bacilli could be found, and on the 23rd, 24th, 25th, 26th, and 27th day from the beginning half-a-pint of the infected water was drunk each day without any ill-effect (Sixth Research Report, Metrop. Water Board, Nov. 1910, p. 7).

If this drinking part of the experiment is to prove anything it would be necessary for Dr. Houston to follow it up by drinking a similar number of fresh typhoid bacilli from the same

patient and contracting the disease, for without this test we have no certainty that Dr. Houston is susceptible to this malady, and, therefore, a fit *corpus vile* on which to make this crucial test.

Vitality of the Spirillum of Asiatic cholera in potable water.—Experiments were made by Houston with the cholera spirillum on exactly the same lines as those which he had previously adopted in the case of the typhoid bacillus in raw Thames, Lea, and New River water. The principal conclusions arrived at may be summarised as follows (4th Report on Research Work, Metrop. Water Board, June, 1909):—

(1) Cholera vibrios die very rapidly in raw Thames, Lea, and New River water as the result of storage in the laboratory. At least 99·9 p.c. perished within one week, and in none of the experiments could any cholera vibrios (recognisable as such) be found even in 100 c.c. of water 3 weeks after its infection. In more than half the experiments the results were negative by the second week.

(2) The isolation of cholera vibrios from artificially infected raw river water presents no insuperable difficulties even when the number artificially added is very small, both actually and relatively to the bacteria nominally present in the river water.

(3) On the other hand, microbes liable (after careful study) to be mistaken for true cholera vibrios were not found in comparable, but non-infected, river water samples examined under precisely similar conditions.

Thus the cholera vibrios are much more perishable in these raw river waters than are the typhoid bacilli under similar conditions.

The comparatively short duration of life of pathogenic bacteria when introduced into natural waters and more especially into surface waters, which these numerous and independent investigations establish, clearly show that the process of storage in large reservoirs must form a very important safeguard against the water-carriage of zymotic diseases. This safeguard, which is supplementary to and quite independent of that of filtration, has the great advantage of being under perfect control and much less liable to accidental disturbances than are most other methods of water-purification. It is, however, unfortunate that many reservoirs attached to water works have not been designed so as to secure the maximum advantages of storage, and their rearrangement with this object in view is generally a matter of great expense and sometimes impracticable. It is to be hoped that in future engineers will be more careful to arrange for such a circulation of the water that each particle of water entering shall remain as long as possible in the reservoir before passing out.

The influence of storage on the bacteriology of surface waters has recently been made the subject of very extended and interesting investigations by Houston in connection with the London water supply. There can be no doubt that adequate storage brings about the following beneficial changes:—

(1) Reduces the number of bacteria of all sorts.

(2) Reduces the number of bacteria capable of growing on agar at blood heat.

(3) Reduces the number of bacteria capable of growing in a bile-salt medium at blood heat.

(4) Reduces the number of coli-like microbes.

(5) Reduces the number of typical *B. coli*.

(6) Alters certain bacteriological ratios for river-waters, e.g. it reduces the number of typical *B. coli* to a proportionately greater extent than it reduces the number of bacteria of all sorts.

(7) If sufficiently prolonged, it devitalises the microbes of water-borne disease (e.g. the typhoid bacillus and the cholera vibrio).

(8) Reduces the amount of suspended matter.

(9) Reduces the amount of colour.

(10) Reduces the amount of ammoniacal nitrogen.

(11) Reduces the amount of oxygen absorbed from permanganate.

(12) Usually reduces the hardness and may reduce (or alter the quality of) the albuminoid nitrogen.

(13) Alters certain chemical ratios for river-waters; e.g. the colour results improve more than the results yielded by the permanganate test.

(14) Has a marked 'levelling' effect on the totality of water delivered to the filter-beds.

(15) Tends generally to lengthen the life of the filters (only under exceptional conditions is the contrary true).

(16) An adequately stored water is to be regarded as a 'safe' water, and the 'safety change' which has occurred in a stored water can be recognised by appropriate tests.

(17) The use of adequately stored waters renders any accidental breakdown in the filtering arrangements much less serious than might otherwise be the case.

The experimental basis for many of the above statements with regard to the benefits of storage will be found in the table on p. 416 (Houston, Annual Report, March 31, 1910, p. 52):—

Fæcal streptococci in water.—Attempts have been made to supplement the indications of faecal contamination yielded by the presence of *B. coli*. The most recent and noteworthy of these is the examination of water for the presence of certain streptococci which are usually very abundant, sometimes even more abundant, in human faeces than is the *B. coli*. This matter has been engaging the attention of Dr. Houston since 1898, and he has (June, 1910) given a special account of the results which he has obtained.

At the outset it should be pointed out that these streptococci are not peculiar to human excreta, but are also abundantly present in those of the higher animals, many of Houston's experiments having been made with streptococci obtained from cow-dung. The study of these micro-organisms does not, therefore, at present put us in possession of that all important desideratum—a means of distinguishing between contamination due to the excrement of man and that which is due to the lower animals.

According to Houston, human faeces contain, roughly, 100,000 streptococci per 1 grm. On the other hand, in some stools streptococci are either absent or present in such small numbers relatively to those of other bacteria that search

cannot, therefore, be regarded as any criterion of its purity. The relative scarcity of streptococci in waters which have undoubtedly received a considerable amount of sewage matters is accounted for by the fact, established by Hous- ton, that streptococci very rapidly die off when placed in water. This circumstance points, of course, to the presence of streptococci serving as an indication of very recent contamination.

Recent bacteriological methods applied to other processes of water purification.—From the evidence already brought forward it appears that confidence in the purification which can be effected by storage and sand-filtration, under favourable conditions, has been distinctly strengthened by the application of the more recent developments of bacteriological water examination—search for *B. coli* and other microbes more or less connected with sewage contamination.

Certain other processes of water-purification which are employed on the large scale may now be briefly considered.

Mechanical filters.—The use of mechanical filters originated in America, and their employment in our own country is becoming more and more common. Such filters are in use at Bolton, Burnley, Heywood, Edinburgh, Crewe, Gloucester, Shrewsbury, and other places in Great Britain, whilst they have also been installed in India, Japan, and some of the colonies. Space does not permit the discussion of the relative merits of the two different processes of filtration. They each possess their advantages and disadvantages; they can each be made to yield good and bad results according to the manner in which they are employed. The following results may serve as an illustration of the very high degree of purification which can be secured

PURIFICATION OF RIVER WATER BY MECHANICAL FILTERS.

	Number of bacteria in 1 c.c.				<i>B. coli</i> (typical) in			
	Gelatin at 20° C.		Carbolic gelatin at 20° C. 7 days	Bile-salt agar at 37° C. 4 days	100 c.c.	10 c.c.	1'0 c.c.	0'1 c.c.
	2 days	7 days						
Raw river water	3700	—	35	19	+	+	+	+
Ditto after passing sand filters	130	405	2	2	+	+	0	0
Ditto after further passing mechanical filters	8	33	0	0	0	0	0	0

by means of mechanical filters, which, in this instance, were employed to further purify a river water, which was being very imperfectly purified by some defective sand-filters.

Clark's process of softening.—Already in 1885 the writer showed that in softening water with lime, a very large proportion of the bacteria are carried down with the precipitated chalk, but that if the latter is allowed to stand in contact with the softened water bacteria again pass from the precipitate into the water. In the softening process this removal of bacteria may, under favourable conditions, amount to upwards of 90 p.c.

Recently the writer had occasion to deal with a chalk well water, which was causing anxiety in consequence of its frequently containing *B. coli* in rather small volumes. The most obvious and unobjectionable method of purification which suggested itself was softening with lime, inasmuch as the water contained plenty of calcium bicarbonate in solution. The following table shows the results obtained in a number of small-scale experiments in which this water was treated with lime, and sometimes with aluminoferric, and in which the softened water was sometimes decanted, sometimes filtered through paper without disturbing the precipitate ('clear filtration' in the table), and sometimes filtered after deliberately disturbing the precipitate ('turbid filtration' in the table).

A great many experiments were made in addition to those recorded below, but always with the same disappointing result, that not-

Vol. VII.—T.

withstanding a large percentage reduction in the total number of bacteria taking place, it was only in rare cases that the *B. coli* was banished from 100 c.c. of the water by the precipitation process. It must be remembered that the demands now commonly made on a purification process with regard to the removal of *B. coli* are much more stringent than with regard to the removal of bacteria in general. Thus, should an untreated water contain 1000 bacteria per 1 c.c., if by treatment the number were reduced to 50 per 1 c.c., this would represent a purification of 95 p.c., and the water would be regarded as quite satisfactory from the point of view of the total number of bacteria present. But, if an untreated water contained the *B. coli* in 0'1 c.c., and after treatment this microbe were not present in less than 10 c.c., this would signify a removal of 99 p.c. of the *B. coli* present in the original water. But so high is the standard of purity at present often demanded in respect to freedom from *B. coli*, that the water which had thus been purified to the extent of 99 p.c. might still be regarded as of a questionable degree of purity.

Ozone treatment.—The bactericidal properties of ozone have long been demonstrated,¹ but it is only in quite recent years that it has been used on a large scale for the sterilisation of town water-supplies. In France the drinking waters

of the towns of Nice, Chartres, and Cosne are being subjected to ozone treatment, whilst a plant for the treatment of 10 million gallons of water was projected in connection with the Paris waterworks. In Germany there are installations at Paderborn, Schierstein, and Hermannstadt.

The writer has made experiments with ozone in connection with the practicability of purifying the chalk well-water to which reference has just been made above. The extraordinary efficacy of this agent will be apparent from the foregoing results obtained in experiments in which the impurities of the chalk

well-water were enormously exaggerated by the addition of 4 p.c. of polluted canal-water.

Bleaching-powder treatment.—The bactericidal action of hypochlorites, again, has been long known, and bleaching powder is one of the

oldest and commonest of disinfectants. The use of hypochlorites for the sterilisation of water-supplies was first brought into prominence in this country by Houston, who used 'Chlorox' which is an electrolysed solution of common

¹ B. coli found absent even in 500 c.c.

salt, for the treatment of the Lincoln water-supply during the memorable epidemic of typhoid which occurred in that city in 1904-5.¹

The writer had occasion some years ago to investigate the efficiency of the bleaching-powder treatment on a chalk well-water, the experiment being made with a large experimental plant.

From the results given above it will be seen what a high degree of purification is obtained by this simple and inexpensive method of treatment, even when extremely small quantities of bleaching-powder are added to the water.

¹ In that epidemic there were as many deaths (119) from typhoid in six months as had occurred from the same cause during the previous eighteen years.

Thus the only occasions on which *B. coli* was found even in 100 c.c. of the treated water was on the first day of each of the two series of experiments and thus when the apparatus had presumably not yet been completely washed out with treated water. On several occasions even 500 c.c. of treated water was examined for *B. coli*, and this microbe was on each such occasion found to be absent even in that large volume.

Similar results have been obtained by Sims Woodhead, Thresh, Hehner, Rideal, and others.

For the more recent experience in the chlorination of drinking water, and for a summary of many other important points, the reader

should consult Houston, Progress in Water Purification, Trans. Inst. of Water Engineers, 27, 1922, p. 117.

Treatment with ultra-violet light.—The known bactericidal action of the ultra-violet rays has been applied by Victor Henri to the sterilisation of water on a large scale. The rays are supplied by a Cooper-Hewitt mercury lamp. The lamp is worked with 3 amperes at 220 volts, and is placed in the bend of a semicircular trough through which the water is passed. At Marseilles the process has been tried with a plant yielding 130,000 gallons per 24 hours, and using 120 watts per 1000 gallons. The crude water always contained some *B. coli*, and the total number of bacteria varied between 30 and 300 per 1 c.c., whilst, in the treated water, *B. coli* was absent and the total number of bacteria was reduced to an average of 1 per 1 c.c. (Modern Methods of Water Purification, Don and Chisholm, London, 1911). See also W. Clemence, Engineering, Jan. 27 and Feb. 3, 1911.

Conclusions.—During the nearly 40 years that the systematic bacteriological examination of water has been practised an enormous amount of work has been carried out by a large number of investigators, but notwithstanding the immense multiplication of results it must be admitted that no very surprising novelties have been brought to light since the year 1895. By then all the salient features in the bacteriology of water had been mapped out, and the past 30 years have more especially been occupied in filling in countless details and in confirming over and over again what had already been broadly established.

Thus, already in the earlier period, the methods of bacteriology had been successfully applied to a determination of the value of the most varied processes of water purification natural and artificial, filtration, storage, precipitation, sedimentation, &c. It had been shown how such processes should, in the interests of public health, be continuously watched over and controlled by bacteriological examinations made at frequent intervals. Again, the vitality in water of the principal bacteria associated with water-borne zymotic disease had been investigated, and the results then obtained were substantially the same as those which have been arrived at by the most recent developments in bacteriological technique. In a word, these most recent developments in the methods of bacteriology have served to confirm and emphasise the conclusions which had been generally arrived at by the less perfect methods of the earlier period.

The all-important questions which the water-examiner has to answer are the same to-day as they have been all along: (a) has the water been contaminated with the excreta of man?; and (b) if such contamination has taken place, has the water in its subsequent history been subject to conditions which would ensure the destruction or removal of the pathogenic bacteria which may at any time be present in such human refuse?

To the first of these questions bacteriology cannot give a categorical answer even to-day, because we are not acquainted with any microbes which are absolutely characteristic of human excreta. The greatly increased facilities for the

detection and quantitative determination of the *B. coli*, however, have undoubtedly placed us in a position to ascertain readily whether and to what extent a water has been contaminated with excremental matter irrespectively of whether the latter is of human or animal origin, but it is obvious that this will not, in general, carry us very far, inasmuch as practically all surface water must be more or less so contaminated.

To the second question a similarly qualified answer, again, can be readily given. If the water is free from *B. coli* in a large volume, it may safely be concluded that *a fortiori* it is free from the typhoid bacillus in a similar volume. But should the *B. coli* be found in a small volume, it does not follow that the water may at any time be liable to contain typhoid bacilli, because the discovery of the *B. coli* does not prove that the water has been contaminated by man at all.

Thus with regard to both questions, it is obvious that we are in a much stronger position in the matter of exculpating than in that of incriminating a water. However, the inference that a water free from *B. coli* in a large volume is, therefore, necessarily a safe one, requires a slight qualification in view of the remarkable and interesting revelations which have in recent years been made with regard to what are known as 'typhoid carriers.' Some of these persons suffering from 'ambulatory typhoid' discharge typhoid bacilli in the urine, and it is thus possible that water may actually become contaminated with typhoid bacilli without at the same time receiving any *B. coli*. Although this is not likely to be of frequent occurrence, still its possibility, especially in the case of men working in wells, filter-beds, and service reservoirs, should on no account be disregarded.

Certainly one of the most important advances made in bacteriology during recent years is the careful characterisation of bacteria by means of biochemical tests, and the isolation of particular types of bacteria from such mixtures as are present in water by means of special culture-media, liquid and solid. However, until bacteriologists have agreed upon uniform tests for each particular microbe it is unavoidable that there should be much confusion and that the results obtained by different observers should be difficult to compare. Under these circumstances the interpretation of results by the individual observer is a matter of the greatest importance, and it is needless to say that unless the individual observer has a wide personal experience and a thorough knowledge of the factors affecting the purity of water-supplies of different kinds his interpretation of the results obtained will not only have little practical value but may easily lead to very serious mistakes.

Thus, whilst the outstanding achievement in bacteriological water examination during the past 25 years is the systematisation of tests for detecting the presence in water of specific bacteria, especially *B. coli*, Streptococci, and the spores of *B. enteritidis sporogenes*, the different possible sources of these bacteria, and their different hygienic significance according to source, render any hard and fast application of standards based on the presence of these microbes impossible without liability to serious errors of judgment being committed.

Space has not permitted reference in detail to the spores of *B. enteritidis sporogenes*¹ as an index of faecal contamination. The figures on p. 411 show how much less abundant in faeces are these spores than is the *B. coli communis*. They do not, therefore, form such a delicate test for sewage contamination as does the *B. coli*, and their final identification is much less certain. The water-bacteriologist should, however, not neglect a search for these spores, but should regard the evidence which their presence or absence affords as supplementary to that which is furnished by the *B. coli* results.

In conclusion a word may be said with regard to the relative value of the chemical and bacteriological examination of water. At the present time it is often supposed that the chemical has been entirely superseded by the bacteriological examination, and that the chemical analysis of drinking water can be dispensed with. In reality the two methods of examination supplement each other. In those cases in which the source and general characters of a water supply are well known, the variations in purity from day to day or from week to week can undoubtedly be more satisfactorily watched by means of bacteriological examination. On the other hand, it is often desired by means of a single examination to ascertain the fitness or otherwise of a water for domestic use, and in such cases the omission of a chemical analysis may lead to an entirely erroneous opinion being formed. The ingredients detected by chemical analysis—organic matter, ammonia, nitrates, chlorides, &c.—on which an opinion as to hygienic quality is based, are all much more permanent and uniform features in the composition of the water than are the amount and the nature of the bacterial life which it may contain. The chemical analysis will, therefore, if skilfully interpreted, enable a much better idea of the potability of the water to be obtained than would be possible from a single bacteriological examination.

There are so many factors and considerations which have to be taken into account if an opinion of any real value as to the hygienic quality of water is to be formed, that no knowledge or information which can be gained either by chemical, or by bacteriological examination, or by inspection of source, or by any other available means whatsoever should be neglected.

P. F. F.

WATER-GAS v. GAS, WATER.

WATER-GLASS. *Soluble glass v. GLASS.*

WATER-OF-AYR STONE v. WHETSTONE.

WATER-SOFTENING. Some natural waters require the use of a relatively large amount of soap to form a lather, and are characterised as 'hard' waters. They contain impurities which react with and destroy soap forming a curdy precipitate, and the generic term 'water softening' comprises all processes which remove these impurities, wholly or in part. Certain processes of water purification or treatment not falling strictly within this definition, are nevertheless so related to true water-softening processes that they are most conveniently considered here.

Effects of hardness.—Hardness renders water unsuitable for many domestic and industrial uses. In washing and scouring, hard water wastes soap and discolours fabrics by the deposition of insoluble salts; in the manufacture of worsteds and woollens it decreases the pliancy of the fabric; in tanning it deposits lime in the hides; when heated or evaporated in kettles, calorifiers, boilers, &c., it deposits scale which impairs heat transmission and increases charges for maintenance and depreciation. Bicarbonate hardness hinders the uniform dyeing of fabrics. Even ice prepared by freezing hard water is unsatisfactory, being opaque, or coloured if iron is present, and leaving a dirty sediment on melting (Behrman, *J. Ind. Eng. Chem.*, 1921, 13, 235).

Nature of hardness.—Hardness may be caused by the presence in water of soluble salts of most metals other than the alkali metals; for example, barium chloride is occasionally found as a major impurity causing hardness. But in the great majority of cases hardness is due mainly to salts of calcium and magnesium, and to a lesser degree to salts of iron and manganese.

It is usual to recognise two types of hardness, temporary and permanent.

Temporary hardness due to bases, usually calcium but occasionally iron, present as bicarbonates, is so called because it is removed by boiling the water, whereby excess carbon dioxide is gradually expelled and the less soluble normal carbonate is precipitated. With regard to certain softening processes which depend entirely on this reaction, it is important to observe that at temperatures below 100°C. but little carbon dioxide is removed unless the water be violently agitated, and that even at 100° some 10 minutes' boiling is necessary for its complete expulsion (Paul, *Boiler Chemistry*, Longmans, p. 94).

Hardness due to magnesium bicarbonate, often regarded as temporary, is less affected by boiling than that due to calcium bicarbonate, normal magnesium carbonate being more soluble than calcium carbonate. On the other hand, at the temperatures attained in boilers, magnesium carbonate is hydrolysed to magnesium hydroxide, which is precipitated and may even be dehydrated to the oxide.

Permanent hardness is that which persists after boiling; it is due to the combined effect of a small quantity of residual normal carbonates and of other salts, chiefly sulphates, nitrates, and chlorides, of calcium and magnesium.

Quantitative estimate of hardness.—Originally hardness was measured and stated in terms of the number of grains of calcium carbonate per gallon of a solution equivalent to the water under test in respect of the quantity of soap required to produce a lather. Hardness corresponding to 1 grain CaCO_3 per gallon (1 part CaCO_3 in 70,000 parts of water) is described as 1 degree (Clark) of hardness. Hardness is now frequently expressed in terms of parts of CaCO_3 per 100,000 parts of water; a quantity evidently equal to $10/7 \times$ the hardness expressed in Clark degrees.

It is convenient to give here a statement (Table I) of the solubilities at about 15°C. of the chief hardening impurities, together with the equivalent concentration of calcium carbonate.

¹ Klein, Local Government Board; Medical Officer's Reports, 1897-8, 1898-9, 1901-2; Klein and Houston, *ibid.* 1899-1900; Hewitt, Trans. Jenner Institute, Series 25, 70; *Trans. State Medicine*, 1904, 12, 158.

in grains per gallon and parts per 100,000, which, evidently, represent the maximum hardness of water which can be caused by each impurity at the ordinary temperature.

TABLE I

Impurity	Solubility. Parts per 100,000	Equivalent hardness.	
		Parts per 100,000	Degrees (Clark)
CaCO ₃ Dissolved	118	118	82.6
MgCO ₃ as bi-	3100	3675	2570
FeCO ₃ carbonates	abt. 400	345	240
CaCO ₃ . . .	6.8	6.8	4.8
MgCO ₃ . . .	abt. 70 ¹	83	58
CaSO ₄ . . .	198.3	145.5	101.8
Ca(OH) ₂ . . .	170	230	161
Mg(OH) ₂ . . .	0.9	1.54	1.08

¹ The solubility of magnesium carbonate varies greatly with the pressure of carbon dioxide; the figure given is for a solution in equilibrium with carbon dioxide at about the partial pressure normally existing in the atmosphere.

Some of the solubility data are uncertain, but the table will serve to give a useful indication of the softening effect of the reactions under consideration. Thus, hardness due to calcium bicarbonate alone, which may in equilibrium with carbon dioxide at atmospheric pressure attain a maximum of 82.6 degrees, can be reduced by boiling to that due to calcium carbonate alone, viz. 4.8 degrees; whilst that due to magnesium bicarbonate which may reach a maximum of 2500 degrees under the above conditions, is, by boiling, reduced only to 58 degrees, equivalent to the solubility of magnesium carbonate.

Water softening reactions.—Temporary hardness is usually removed by the addition of lime, as originally advocated by Clark in 1841, and applied by J. H. Porter in the 'Porter-Clark' process (J. Soc. Chem. Ind. 1884, 3, 51). The chief reactions involved are:

From Table I it appears that the residual hardness in a solution saturated at 15° with calcium carbonate and magnesium hydroxide would be 5.9 degrees. In practice the reactions are not complete and it is difficult to avoid a slight excess or deficit of lime, but the minimum hardness actually attained at 15° is about 3.5 degrees.

Lime precipitates as hydroxide any magnesium present as sulphate, chloride, &c., but an equivalent amount of calcium remains in solution; lime does not, of course, react with calcium salts: hence permanent hardness is unaffected by the lime treatment.

Permanent hardness due to calcium salts may be treated by addition of sodium carbonate (soda ash), which precipitates calcium as carbonate, leaving in solution sodium salts of the acidic radicals with which it was combined; thus, e.g.

The origin of this use of soda ash is obscure, but it is clear that P. A. Maignen was one of the first to employ it, as a powder with lime and steam (J. Soc. Chem. Ind. 1896, 5, 22). Sodium

carbonate also removes temporary hardness due to calcium bicarbonate:

but the method has the disadvantage of leaving sodium bicarbonate in solution and is relatively costly.

Reference to Table I shows that addition of sodium carbonate cannot reduce permanent hardness due to magnesium below the 58 degrees, due to the solubility of magnesium carbonate. Such hardness is best removed by the addition of caustic alkali, or, what is equivalent and cheaper, lime and soda ash in equivalent proportions. The reaction involved is of the type:

Should a water have only permanent hardness due to magnesium salts the use of caustic soda has the advantage of leaving no residual hardness due to calcium carbonate. In the equally unusual case where the bicarbonate hardness is exactly two-fifths of the total hardness, caustic soda alone will soften the water according to the following reactions:

Certain other reagents merit brief mention. Borax, sodium silicate, and sodium phosphate can precipitate calcium and magnesium as the relatively insoluble borates, silicates, and phosphates; the two former are common ingredients in washing powders, but none of the three is used in industrial water-softening. Barium hydroxide is an effective softening reagent, especially if the impurity in water is chiefly sulphate, but its high cost and poisonous character hinder its general use.

A suspension of barium carbonate in milk of lime has been patented as a softening reagent (H. Reiser, D. R. P. 333994, 1918) and is used in certain plants by Royles; it has the advantage of yielding a water of minimum hardness even where precise adjustment of the quantity of reagent is not attained, but is liable to acquire a coating of barium sulphate, rendering it inactive.

Permutite, or artificial zeolites, form a distinct class of water-softening reagents. They are hydrated aluminosilicates of soda, similar in composition to naturally occurring zeolites, e.g. *analcite*, $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. Such compounds, in contact with aqueous solutions of metallic salts, enter into reversible reactions of the type:

With dilute solutions of salts of the heavier metals, such as hard water, the reaction is almost complete toward the right; with concentrated solutions of sodium salts, e.g. brine, the reverse reaction largely preponderates. The utility of such reactions in water-softening is obvious, and their application is discussed below.

Though some waters are naturally softened by percolation through strata containing

zeolites, these minerals undergo base-exchange but slowly and to a small extent. The artificial zeolites, on the other hand, undergo base-exchange readily and to a large extent, and this has been attributed by Gans to a difference in constitution of the kind indicated by the following formulae:—

Permutit was first prepared by Gans (D. R. P. 174097, 1905) by allowing alkali aluminate free from uncombined alkali to act on hydrated silicic acid, employing heat to complete the reaction. Calcium permutit is formed by treating the product with calcium chloride solution to replace soda by lime.

Numerous methods for preparing similar reagents have since been described, for details of which the patent literature must be consulted. The more important methods consist (a) in fusing together convenient ingredients to yield the desired composition, e.g. 3 kaolin, 6 quartz, and 12 soda-ash (J. D. Reidel, D. R. P. 186630, 1906; see also D. R. P. 200931, 1907); or (b) in hydrating by high pressure steam, with or without the addition of alkali, natural minerals of appropriate composition such as trass, phonolite, leucite, sodalite, &c. (Permutit Filter Co., Eng. Pat. 26094, 1910; see also, re similar hydration of Portland cement, Snelling, U.S. Pat. 1325213, 1919); or (c) in effecting base-exchange by the action of metallic salt solutions upon primary products obtained as above.

Some other base-exchange reactions deserve mention. Sodium permutit removes ammonia from water; if sodium permutit be treated with dilute acid it becomes an acid permutit, which will remove soda and produce an acid water; calcium permutit removes manganese from water. If calcium permutit be treated with a solution of a manganese salt and the resulting manganese permutit be acted upon by a solution of calcium permanganate, reactions of the following type occur:

producing a dark-coloured mass containing both lime and a highly oxidised manganese group. This is, in effect, an insoluble permanganate and can serve either to sterilise water or to eliminate any iron it may contain by precipitation as ferric hydroxide which is retained upon the surface of the filter-bed (J. D. Reidel, A.-G., Fr. Pat. 405900, 1909; R. Gans, Eng. Pat. 21184, 1909). A zeolite in which soda has been substituted by stannous oxide will reduce gold from solutions of its salts and retain it as purple of Cassius. Thus it is evident that base-exchanging reactions are known of the most diverse character and applicable to many purposes.

A number of processes have been described

in which iron is removed from water by aeration effected by allowing the water to flow down towers packed with coke, or by spraying it through nozzles. In this way the iron is oxidised to the hydroxide, which remains in colloidal solution until it is coagulated and removed by the action of the material forming the filter bed. Too much aeration is to be avoided if the water contains a relatively large proportion of lime and carbon dioxide, or the latter may be driven out of the water leaving insufficient to hold the lime in solution as bicarbonate, with the result that calcium carbonate is precipitated and blocks the pipes (Kisskalt. Gas- u. Wasserfach, 1924, 67, 3; J. Soc. Chem. Ind. 1924, 43 B. 230).

Treatment of alkaline and acid waters may be briefly considered. There is no practicable method for the removal of alkali, but various reactions, e.g. addition of calcium chloride or sulphate in the form of a strong solution or as water containing permanent hardness, will serve to convert alkali carbonate or bicarbonate to a neutral salt, but the resultant water will evidently be undesirable as a boiler feed water.

Acid waters derived from moorland catchments may dissolve lead; this tendency may be corrected either by hardening the water with lime or, better, by Thresh's method of adding sodium silicate, which removes plumbo-solvency without increasing hardness.

Artificial hardening, by addition of calcium sulphate, is practised in some cases to render a soft water supply more suitable for use in brewing.

Boiler compositions contain either or both (a) ordinary softening reagents such as lime, soda-ash, and caustic soda, and (b) organic matter, e.g. tan bark, which serves, by mere mechanical action, to prevent the formation of hard scale. Reagents of class (a) may be dismissed with the comment that they are usually dearly bought in the form of boiler compositions and that, in any case, it is unsound to perform water-softening reactions within a boiler. Materials of class (b) are evidently the lineal descendants of the dead pigs our forefathers are reputed to have put in boilers to prevent scale formation (P. G. Jackson, Boiler Feed Water, Griffin, 1919, p. 28).

If a mechanical preventive of scale is desired, undoubtedly the best is pure graphite applied as a cream with water to the clean internal surface of the boiler and subsequently introduced with the feed water at the rate of about $\frac{1}{2}$ lb. per day (Hinchley, Notes on the Economical Management of Small Boiler Plants, Proc. Chem. Eng. Group, (Soc. Chem. Ind.), 1919; but see, for a scientific investigation of the mechanical effect of linseed, Brun, J. Soc. Chem. Ind. 1919, 22, 76; R. Heuss, Zeitsch. ges. Brauw, 1918, 41, 200).

Proportions of reagents.—In the great majority of cases water is treated with a mixture of lime and soda-ash in such proportion that hardness due to bicarbonates and to magnesium is completely removed by lime, and the hardness then remaining by soda-ash. The amount of reagent required for 1000 gallons of water for each grain per gallon of the various impurities is given in Table II (Paul, Boiler Chemistry, p. 99).

If magnesium salts are to be removed as hydroxide the appropriate quantities of both lime and soda-ash should be used. Quantities of reagent calculated from the table are evidently minima, and in practice a slight excess, about 5-10 p.c., should be used, and the treated water should be faintly alkaline to phenolphthalein.

TABLE II.

Impurity (Present in a concentration of 1 grm. per gallon)	Calcium hydroxide required; lbs. per 1000 gallons	Soda-ash (Na_2CO_3) re- quired; lbs. per 1000 gallons
Free carbon dioxide.	0.260	—
CaSO_4	—	0.111
$\text{Ca(NO}_3)_2$	—	0.092
CaCl_2	—	0.136
MgSO_4	0.095	0.126
$\text{Mg(NO}_3)_2$	0.077	0.102
MgCl_2	0.120	0.159

Emphasis should be laid on the conclusion, following necessarily from the preceding discussion, that the nature and proportions of water-softening reagents cannot be determined simply upon data of temporary and permanent hardness; for the best results it is necessary to have a complete analysis of the water.

Purity of reagents is desirable in all water-softening processes and essential where the proportion of reagents is adjusted directly or indirectly by weighing.

Commercial caustic lime may be of almost any degree of purity. Some samples contain magnesia, some silica and alumina, and in all the content of real lime may vary from 100 p.c. to 70 p.c. or less by absorption of moisture. A much more reliable reagent is calcium 'hydrate,' slaked lime, which, when obtained from trustworthy sources, always contains about 70 p.c. of CaO , will not easily absorb more water, and is a fine powder, convenient for storage and use. If raw quicklime is used, each batch should be tested.

Sodium carbonate is obtainable commercially as the anhydrous salt, soda-ash, and as various hydrates, and may contain impurities such as sodium sulphate or chloride, detrimental to its use in water softening. It should be bought under guarantee or be subject to test before use.

Similarly, caustic soda is easily procured in a state of sufficient purity for water-softening; but it should preferably be in the form of 'flake' or powder for convenience in handling, storage, and measurement.

[In the succeeding paragraphs names given in italics in brackets, thus (*Paterson*), are those of plants or processes which embody the feature under discussion.]

Municipal and domestic water softening and filtration is directed to the production of water free from bacterial contamination and suspended matter, free from colour and from excessive hardness. Owing to its cost, water softening of municipal supplies is practised only in exceptional cases, e.g. with Kentish waters of extreme hardness, derived from the chalk. It is usually effected by an intermittent process in which softening reagents are added to and mixed with a large bulk of water, the precipitate being separated by settlement and decantation; but some small municipal supplies are softened in

large continuous automatic plants of the usual industrial type described below.

Conversely, some large industrial supplies are treated by the intermittent process, using steam to assist solution of reagents and compressed air agitation to ensure their uniform admixture with the water under treatment (*Archbutt and Deeley*). After settlement, the treated water is drawn off by a floating syphon and carbonated by a counter-current of carbon dioxide passed through the outflow pipe (*Proc. Inst. Civ. Eng. 1898, Part 3, p. 404*). Such intermittent systems when properly controlled are probably the most accurate means available for water softening (*E. V. Chambers, J. Soc. Dyers and Colourists, 1918, 34, 240*). They necessitate considerable attention in working and require large tank space, and thus are costly, unless, as in municipal processes, large quantities of water are treated and existing reservoirs can be used.

Domestic water softening is quite commonly practised, and, unless on an unusually large scale appropriate to automatic continuous plant, is also best effected intermittently. Measured bulks of reagent powder are mixed by hand with 5-10 gallon lots of water, the precipitate is allowed to settle and the softened water is withdrawn through a filter (*Maignens*) or by slow decantation (*Wilson-Perrett 'Pukka'*).

One small plant, which may be mentioned here, softens water by heating to about 80°-90°, partly by heat-exchange with treated water, partly by direct heat, the scale being deposited in a tower upon plates removable for cleaning (*Lawrence*). This treatment effectively sterilises water (*Hatch, Proc. Inst. Civ. Eng. 1906*).

Bacteria and suspended impurities are usually removed by filtration. For small domestic supplies this is sometimes effected through porous earthenware filters under pressure, and it is clear that the 'stream-line' filter, which is capable of removing bacteria and even colour from water, could be applied to the purpose (*Hole-Shaw, Proc. Roy. Soc. 1923, 103A, 556*). Wood wool, prepared asbestos wool, cloth and sponges are sometimes employed as filtering media, but practically all large-scale water filtration is effected by beds of sand, preferably quartz sand, carefully graded and supported by a layer of gravel. Filtered water is drawn off either by supporting the gravel layer upon a perforated metal plate or by providing in that layer an effluent pipe system, provided with numerous screened orifices. Wood wool filters are cheaper to install, but the difficulty of cleaning them satisfactorily necessitates periodical renewal, the cost of which must be taken into account.

Large slow sand filters are usually cleaned by laying off units of the filter periodically and removing by hand the top layer of sand. This is continued until the sand bed is so diminished as to require renewal. Rapid sand filters of the gravity or pressure type can easily be cleaned by reversing the flow of water and agitating the sand violently. Agitation is effected in some small plants by hand, in the larger plants by compressed air or by the stream of wash-water itself. A typical illustration is the *Paterson* gravity filter, shown in Fig. 1, in which the steam-jet air-injector is used to

stream of compressed air through the manifold strainer system *ss*, thus agitating and cleansing

Fig. 1.

the filter bed, whilst the dirty water is drawn off by the annular trough *r* to the water outlet *w*.

Fig. 2.

The Vickers' drifting sand filter very ingeniously effects a partial cleansing of the sand-bed while in operation, and is adaptable to

gravity or pressure filtration on any scale. Fig. 2 illustrates a single unit pressure-filter. In normal operation raw water admitted by the valve *A* enters the filter at *B* and passes first through the loose mass of slowly drifting sand *C*, and then through the stationary sand-bed *D*, to the manifold *E*, and the filtered water outlet *F*. Sand is continuously extracted by the pipe system *G*, and conveyed by the pipes *H* to the sand-washer *J*, where it is washed by the incoming raw water and a small quantity of dirty water passes away by the outlet *K*, whilst the main flow of raw water carries the cleaned sand back to the filter at *B*. Valves are provided to permit agitation and washing of the whole filter bed when necessary, the advantage of this type of filter being that, under any given conditions, the interval between such washings is much greater than with ordinary filters.

Efficient working of sand-filters depends upon the formation of a superficial film, composed of the suspended matter derived from the water, which is the effective filtering medium. Where the impurities in water are so small in amount, or of such a nature, that this film is not easily formed, filtration is frequently assisted by the previous addition of 'coagulants,' such

Fig. 3.

as aluminium sulphate. This salt, usually used in the crude form, known commercially as 'alumino-ferrie,' is hydrolysed in dilute solution, especially in the presence of bicarbonates, forming aluminium hydroxide, which rapidly coagulates and carries down suspended matter otherwise unfilterable, and also, by adsorption, removes colouring matter present in the water. Precipitation is best effected in a neutral solution (hydrogen ion concentration $P_H 7$), but is not complete even with the addition of an amount of lime equivalent to the aluminium sulphate (Hannan, Chem. Met. Eng. 1921, 24, 728; 25, 502). Similar results may be attained by the use of the clear 'aluminium hydroxide solution' produced by mixing aqueous solutions of aluminium sulphate (40 grm. in 80 c.c.) and sodium carbonate (10 grm. in 40 c.c.), which, on dilution, precipitates the hydroxide in a form which settles readily (J. W. Coxe, Met. & Chem. Eng. 1923, 29, 379).

Adjustment of the supply of coagulant is effected in pressure filtration by control of the small acid-resisting pump which delivers it into the plant, and in gravity filtration by float-controlled valves. A typical coagulant supply gear of the latter type is illustrated in Fig. 3 (Petersen), the float *v* controlled by the head of

water at the weirs with actuating taper valves *vv* (shown enlarged at (a)) so contoured as to permit, for any flow of water, a corresponding flow of coagulant by the *ss* pipes to the trough where baffles *b* cause intimate admixture with the water.

Automatic water-softening plants.—Many types of these plants are in use, differing in the means employed to effect the fundamental operations into which water softening processes are divisible, viz. (1) preparation of reagents, (2) apportionment of reagents to water, (3) mixing, and (4) settlement and filtration to remove precipitated impurities. For the better consideration of the methods to be described, it is desirable to bear in mind the following essential features of an ideal lime-soda softening plant. Preparation of reagents must be conveniently effected, preferably by automatic means, and should be so made and used that they remain of precisely the same concentration until wholly consumed. Measurement of reagents in relation to water must be accurate over long periods and at all rates of flow, and must yet permit of ready and precise adjustment. Mixing must be speedy and thorough. The reaction tanks must be of such capacity that ample time (preferably at least 2 hours) is allowed for completion of the softening reactions before the water leaves the settling tank, and of sufficiently large cross-section to permit proper settling of the precipitate. The filter should be efficient and readily cleansed, but should only be supplementary to efficient sedimentation.

(1) *Preparation of reagents.*—Occasionally reagents are used in the form of a dry powder, usually purchased ready mixed from the manufacturers of the plant or from a firm specialising in the supply of such prepared reagents. In the great majority of cases they are applied as solutions or suspensions in water, which are commonly made by direct weighing and measurement, mixing or solution being effected, in the smaller plants by hand, and in the larger plants by mechanical stirrers or injector agitators, in a tank at ground level (see Figs. 14 and 15), from which they are pumped to a supply tank above the plant.

Sometimes lime is used in the form of clear lime-water prepared in an automatic solutioner, consisting essentially of a vertical tank, having for the whole (*Boyle*) or part (*Harris-Anderson*) of its height the form of an inverted cone (Figs. 16 and 17). By means of a pipe leading nearly to the bottom, the tank is charged from time to time with a sufficient excess of a cream of slaked lime and water, and a stream of water admitted at the apex of the cone flows upward, first agitating and dissolving the lime, and later, as the cross section of the tank increases, depositing excess lime and all impurities, so that clear saturated lime-water overflows at the top. Accumulated impurities are removed from time to time by a sludge cock. The use of saturated lime-water is attended by certain difficulties which must be recognised in order to attain good results. Owing to the small solubility of lime, a considerable proportion of the raw water, sometimes 15-25 p.c., must be by-passed to the lime solutioner, which is, therefore, of considerable capacity. Sometimes the lime, probably because it is of a lumpy character

and unsuited to the process, becomes 'coated' with carbonate and fails to maintain saturation. Lastly, in cases where the temperature of the raw water varies, care must be taken to adjust the proportion flowing to the lime solutioner, so as to compensate for the considerable variation of solubility of lime shown in Table III (Paul, *l.c.* p. 96).

TABLE III

Temperature, Fahrenheit	Calcium hydrate $\text{Ca}(\text{OH})_2$, grains per gallon
32°	132.1
40°	128.0
50°	121.7
60°	115.5
70°	110.9
80°	107.7
90°	103.6
100°	100.0

(These figures do not agree with the absolute solubility given in Tables I and II, but probably correctly represent the variation of solubility with temperature.)

Fig. 4.

One type of plant has a very ingenious solutioner to prepare automatically from solid soluble salts unsaturated solutions of any desired density (*Harris-Anderson*). It consists essentially of three coaxial tubes, 1, 2, and 3 (Fig. 4), contained in a cylindrical tank 4, forming a central chamber *A*, and three annular spaces *B*, *C*, and *D*, all intercommunicating at the bottom. Solid contained in the bucket *D*, having a gauze bottom, dissolves readily in the water in *A*, owing to gravitational convection. Fresh water, introduced at the top of the annular space *B*, rises at the bottom

with strong solution from A, and flows up the outer space D, to the outlet C. The relatively heavy solution in D balances a greater height of water in A, and the tube B is set, by means of the screw and nut H, at such a height that when the density of the solution in D reaches the desired value, water begins to overflow the lip J on tube 2, and, passing down the space C, mixes with the effluent solution and maintains the desired concentration in D.

(2) *Measurement of reagents.*—The numerous methods employed fall into two broad classes.

Of the plants using clear solutions of lime and soda, some prepare either or both of these as described above, whilst some rely on the displacement of the proper amount of a previously prepared soda solution by the quiet inflow of a corresponding amount of water at the top of a

water required to make saturated lime-water, whilst a small cup L, of fixed size, withdraws a smaller proportion of the water to the soda solutioner, the proportion of soda added to the water being controlled by adjustment of the density of the solution as described above.

In plants using lime suspensions, with or without the addition of soda, the commonest

FIG. 5.

'displacement tank,' from the bottom of which a pipe conducts the soda solution to mix with the water under treatment (Figs. 16 and 18). In either case the raw water is divided into one large stream and two smaller streams, of the proper size to make or displace the required quantities of lime and soda solutions. This division is effected by micrometer valves in the base of a common supply tank (Boyle, Fig. 16) or by a turbo-distributor (Harris-Anderson). In this distributor (Fig. 5) a circular tank A, floating on water in B, and free to rotate under guidance by the roller bearings C on the shaft D, receives the whole supply of raw water which flows out tangentially by the orifices E, F, causing A to rotate: the water is thus distributed evenly over the annular trough G at all rates of flow. Radial partitions, one of which is adjustable, divide off a sector of the annulus, of such size as to separate precisely the fraction of the

FIG. 6.

measuring device is some form of tipping bucket, actuated by the main flow of water, and actuating cups or scoops which supply a definite quantity of reagent to each charge of water passing. Typical examples of this device in its simplest form occur in the Boly and Becco-Legg plants, the latter being illustrated in Fig. 6, where A is the tipping bucket which, after emptying, returns to the normal position

FIG. 7.

shown, and in so doing actuates the arm carrying the chemical scoop B, which discharges into A by a channel C, and agitates the suspension in the chemical tank D by means of the stirrer E. In the Boly plant the contents of the chemical cup (Fig. 7) are variable by vertical screw adjustment of the overflow tube A. Some plants (Lassen-Hart, Peterson, Wilson-Perrin) use double tipping buckets, illustrated by the

Paterson 'Oslameter,' Fig. 8. In the Lassen-Hjort plant the tipping bucket actuates a piston valve supplying reagent.

Special devices are employed in most cases to increase accuracy and decrease wear and tear;

FIG. 8.

thus in Fig. 8, it is seen that the tank has some freedom of movement before it touches the arm A operating the chemical supply gear, whilst an extension lip B on the bucket enables a small addition of water finally to overturn it; and the resulting shock is diminished by the brake paddle C, and absorbed by the rubber buffer D. The Lassen-Hjort tipper has a lock, actuated by

so float in the bucket, which releases the latter when it has a definite content of water; and is buffered by a brake-paddle and springs.

Despite such devices, all tipping buckets are noisy, and in large sizes are impracticable owing to heavy wear and tear. Therefore it is

FIG. 9.

customary in the larger plants to sub-divide the main flow of water so that the measuring gear passes but a fraction of the water, whilst the remainder operates stirring gear in the reagent tank. Fig. 9 shows the Paterson bye-pass Oslameter; a dividing plate A at the weir B takes a small fraction of the water to the tipping bucket C, and sends the remainder over the

FIG. 10.

wheel D, driving the stirrers X carrying cups S, which maintain a supply of reagent to the actual measuring cups X. The Wilson-Ferriss plant, shown in Fig. 10, passes a large part of the raw water direct to the mixer X

by the main F, and divides the residual flow from the perforated pipes A, between a larger tipping bucket Z, driving the paddles C, and a smaller bucket D actuating by wheel and chain the chemical cups S.

A plant made by Wright's Forge and Engineering Co., Ltd. (Fig. 11), passes part of the water from a dividing box A through a bucket wheel B, driving a chain elevator C, carrying chemical scoops D, dipping into the reagent tank E. Another by the same maker (Fig. 12) uses the wheel B to drive by chain and bevel gearing, G, a screw M working in an oil-bath which lowers the discharge pipe H in the chemical tank, and so delivers reagent in proportion to the water passing. The Kennicott proportioning gear (Fig. 13) uses a small definite proportion of the raw water to lift the float F in the regulating tank T, whereby the cord G lowers a

FIG. 11.

slotted discharge pipe F in the chemical tank, the contents of which are agitated by means of a separate water wheel.

In the foregoing plants the proportion of reagent is adjusted by altering the proportion of water passing to the measuring gear, by changing the volume of reagent added or by varying the concentration of the reagent suspension.

Certain plants use a tipping bucket or water-wheel to deliver reagent in the form of dry powder, either from a hopper (Becco-Legg, Maignens, Selys) or by continuous rise of a piston in a

vertical cylinder, having a scraper to strike off the powder flush with the top (Tate and Bell).

(3) *Mixing and precipitation*.—Reagents and water usually flow together into the precipitation tank, sometimes along a channel provided with baffles (see e.g. Fig. 3), and are thereby mixed. Liquid reagent is frequently discharged into a tipping bucket as it begins to fill, and is thus agitated by and with the inflowing water, mixing being completed by the very turbulent

FIG. 12.

outflow when the bucket tips. Some further mixing occurs in most plants by the relatively rapid flow of the water through the channel or pipe leading it down into the settling tank.

(4) *Clarification and filtration*.—Separation of the precipitate is always chiefly effected by settlement, during the slow passage of the water up or along the settling and reaction tank, and completed by filters. These tanks and filters determine the general form and disposition of the plant in one of two commonly occurring types, characterized as 'horizontal' and 'vertical', respectively.

A typical example of the horizontal type, the Lassen-Hjort rectangular softener, is shown in Fig. 14. Water, carrying reagents discharged by the proportioning gear *a* already described, passes down the reaction chamber *b*, up the first settling tank *c*, and through the first

FIG. 13.

wood-wool filter *d*, overflows down channels *ee*, and passes upward through the second tank and filter, *f* and *g*, and finally overflows into

the storage tank *h*, in which a ball-cock *k* maintains a constant level by controlling the raw water supply. Sludge is removed by cocks

FIG. 14

the operation of which is assisted in many plants (*Bobb, Paterson*) by hand agitators.

The vertical type is illustrated by the *Paterson* plant shown in Fig. 15, the mode of

operation of which is obvious from the preceding description. Here also a wood-wool filter is used.

Sand filters have the advantage that they

are more efficient and more easily cleaned than wood-wool filters. The Royle plant, shown in

FIG 15

Fig. 16, affords an example of their incorporation in a vertical plant, and is interesting also as

FIG. 16.

containing an automatic washing device which merits description. Raw water enters the distribution tank A, where the three micro-

meter valves, 1, 2, and 3, pass the major portion of the water to the reaction tube B, a smaller portion to the lime dissolver C, and the smallest portion to displace soda solution in the tank D. These reagents mix in B, with the water which then rises slowly, and is clarified by settlement in E, and then overflows down F to the filter chamber G, passes through the sand filter H, rises to the tank I, and overflows at L. As sediment accumulates on H, the head of water in F, necessary to maintain the required rate of filtration, increases, and the corresponding rise of water in the outer tube M finally sets the syphon O in action and causes a heavy back-stream from I to flow through the filter, thoroughly agitating and cleansing the filter bed.

External independent filters have the great advantage of ready accessibility; their use is illustrated by the Harris-Anderson plant, shown in Fig. 17, where A is the turbo-distributor,

FIG. 17.

B the lime solutioner, and C the soda solutioner, already described, D is the reaction tube, E the settling tank, and F the external filter.

All the foregoing types of plant are open, and thus cannot deliver water at a pressure greater than that due to the height of the outlet above the point of application. Where it is desired to utilise a natural or forced head of water without material loss, a water-softening plant may be enclosed in the manner illustrated by the Royle's plant in Fig. 18, which differs from that of Fig. 16, in that the function of the head tank and micrometer valves in the latter is now performed by the dial cocks 1, 2, and 3, that the tops of C, D, and E are enclosed, that pumps are fitted to charge the reagents into C and D, and that the automatic washing arrangement is eliminated.

By the introduction of waste steam or hot condensates into the mixing chamber (not via the measuring gear), most of the above plants, though sometimes described as 'cold-process' plants, can be used for the hot softening of water. This is frequently advantageous, both

as a means of conserving heat and because a softener worked hot will yield water of lower hardness than one worked cold.

There are, however, a number of plants specifically designed to combine the functions of exhaust steam feed-water heating, water-softening and oil elimination, of which that

FIG. 18.

shown in Fig. 19 (Royle's) is an example. Some plants rely solely upon heating to soften the water (Lawrence, Erith's Recording Heater), but usually the water is treated also with soda or lime and soda, and if necessary with aluminium sulphate (Erith's, Wright's 'Neptune,' Royle's Type E, Kennicott, Lassen-Hjort, Harris-Anderson).

In Fig. 19 the crude water supply, controlled by the ball-cock A, is distributed in B, and part taken to displace soda and aluminium sulphate solutions in C and D respectively in the usual manner. Water and soda flows down through and over a series of dished plates EE, in parallel current with exhaust steam introduced at F, via an oil-separator G, any excess steam passing to atmosphere by the pipe H. Most of the hardening impurity is deposited on the plates EE, which are easily removable for cleaning. Aluminium sulphate is added in the mixing tube at K, and the water finally passes through a settling tank L and filter M as usual.

Brief reference may here be made to much work that has been done upon the 'degassing' of boiler feed-water, as a consequence of the general recognition of the fact that dissolved oxygen is the essential active agent in the corrosion of boilers and other steam plant. Two methods have been proposed, in various forms, for its removal; depending respectively upon boiling it out at atmospheric or reduced pressure, and upon causing it to combine with iron in the form of scrap-iron, iron-manganese alloys, or couples of iron with zinc or copper (see e.g. Warner, Eng. Pat. 7272, 1915; Wilson and Anti-Corrosive Eng. Co., U.S. Pat. 1387748, 1921; and Heile, D. R. P. 306388, 1916;

L. and C. Steinmüller, D. R. P. 320893, 1917; Hartung, D. R. P., 368645, 1918; Bailey, Morgan and Met-Vickers' Elect. Co., Eng. Pat. 194942, 1921. For a full discussion see Kastner, Proc. Inst. Mech. Eng. 1921; J. Soc. Chem. Ind. 1921, 40, T. 67).

Zeolite water-softening plants.—These plants make provision for the filtration, or, rather, percolation, of water through a bed of granular zeolite, and for the periodic regeneration of the zeolite by means of brine; they are, therefore, essentially very simple and conform to the type (United Water Softeners, Ltd.) illustrated in Fig. 20. Water enters by a meter A, and, valves 1 and 4 only being open, passes in at the top of the closed reagent tank B, down through the

FIG. 19.

bed C of zeolite, supported upon a layer of quartz sand D, and thence to the main. When the meter indicates that the apparatus has treated the maximum quantity of water (calculated with regard both to the quantity of zeolite and to the initial hardness of the water), the cocks are manipulated so as to (1) drain

the water wholly from the tank, (2) introduce, by means of the steam injector *m*, the proper charge of brine previously prepared in the wooden tank *g*, and (3) to drain and wash the salt from the zeolite bed. This done, cocks 1 and 4 are again opened, all other cocks being shut, and the plant again functions as a water-softener.

Comparison of soda-lime and zeolite processes.

—Each process has its peculiar advantages and limitations, which broadly determine its field of use and may be summarised as follows:—

With efficient plant, properly operated, the residual hardness of treated water should be 3–5 degrees for the cold soda-lime treatment, 1–3 degrees for the same process worked hot, and 0–1 degree for the zeolite process.

Dissolved solids are diminished by lime-soda treatment, but increased by zeolite softening,

owing to the substitution of sodium salts for calcium salts.

Treatment of water containing iron or sediment presents no difficulty in the lime-soda process, as these impurities are removed with the precipitate in the normal course of working. Such waters, however, must be freed from iron and sediment before entering zeolite softeners, to avoid the formation of a deleterious coating on the active material.

Cost of plant for lime-soda treatment depends only on the maximum hourly flow of water, whilst for the zeolite process it depends also on the hardness of the water. It is also affected by the fact that stoppages for regeneration of a zeolite plant are more frequent and of greater duration than those for cleaning of a lime-soda plant.

Cost of treatment is about the same for removal

FIG. 20.

of permanent hardness by either method, but temporary hardness is removed by lime at about one quarter the cost of its removal by zeolite.

From the foregoing characteristics it appears that in the textile, dyeing, and laundry industries, where minimum hardness is the first consideration, zeolite softening is the more suitable. In many such cases, where the water contains iron or sediment, and has any considerable temporary hardness, it is advantageous to treat it first with lime in a precipitation softener and then remove residual hardness with zeolite. If this is done, ample reaction space must be provided in the lime softener, as any excess lime may hinder the operation of the zeolite softener and produce a turbid effluent.

The lime-soda process is the better for boiler-feed water, for municipal softening, and for water to be used in ice manufacture. Its suitability for municipal softening is determined by its low cost and by the possibility of applying it in existing installations. For boiler-feed and

ice manufacture reduction of dissolved solids is of primary importance, and this requirement is best met by the precipitation process. Where a raw water contains much bicarbonate hardness, the quantity of alkali bicarbonate produced by zeolite softening may cause serious alkalinity and priming in boilers. (For a fuller discussion of these matters, see Blumenthal, *Zeitsch. angew. Chem.* 1921, 34, 189; and Behrman, *J. Amer. Waterworks Assocn.* 1923, 10, 623; Memoranda by the Chief Engineer to the Manchester Steam Users' Association, 1903, and 1917–18; for a discussion with special reference to the textile industries, see King and Chambers, *J. Soc. Dyers*, 1918, 34, 240–247.)

WATER STONES v. AGATE.

WATERS, AERATED v. AERATED WATERS.

WAVELLITE. A mineral consisting of hydrous aluminium phosphate $3Al_2O_3 \cdot 2P_2O_5 \cdot 12H_2O$, forming globular or stalactitic masses with an internal radiating structure. The colour is

white, yellowish, or green; sp.gr. 2.32. The mineral usually occurs on the joint faces of slaty rock, and was first observed in the eighteenth century by Dr. W. Wavell in the slates at Fillsigh near Barnstaple in Devonshire. Good specimens have also been found in Co. Cork. In larger amounts it occurs in Arkansas and Pennsylvania. At South Mountain in Pennsylvania it has been mined for use as a fertiliser and as a source of phosphorus, used locally for making matches. L. J. S.

WAX-OPAL v. OPAL.

WAXES, ANIMAL AND VEGETABLE.

These waxes are a group of substances resembling beeswax in their physical properties; they are mixtures of compounds composed of the elements carbon, hydrogen, and oxygen. Waxes of mineral origin, such as paraffin wax, ozokerite, ceresin, and montan wax, are described elsewhere. Physically the waxes come in the series (1) fixed oils, (2) soft fats, (3) tallow-like substances and solid fats, (4) waxes, and (5) resins. The waxes all melt below 100°. The waxes differ from the fats in having little or no greasiness at ordinary temperatures. The greasiness of most of the fats is probably due to their containing some olein (glyceryl oleate) or some glyceryl esters of unsaturated fatty acids. There was an impression in the last century, doubtless produced by Chevreul's work on the fats, that whilst the fats contained glyceryl esters, the true waxes did not, but contained esters of higher members of the $C_nH_{2n}O_2$ series of acids with alcohol radicles other than glyceryl. As a result of this an unfortunate system was introduced of denying the name of 'wax' to those waxes that are largely composed of glycerides, and of calling them 'tallows.' It serves no useful purpose and has the effect of upsetting the ordinary meaning both of 'wax' and of 'tallow.' By it, on the one hand, Japan wax was to be called Japan tallow and myrtle wax was to be called myrica tallow, because they are both largely composed of glyceryl palmitate; and on the other hand, sperm oil was to be described as a liquid wax, because it was thought to contain very little glyceryl esters. Refined wool fat, a soft unctuous substance, was called wool wax. The inadvisability of attempting to alter the meaning of a word in common use to suit some special scientific classification was pointed out by Gregory in *Nature*, 1911, 87, 538.

Beeswax and most of the vegetable waxes seem to be produced by the integuments of the organisms and not internally, and their value to the plant is to repel water or resist its action and prevent its ingress or egress. Beeswax, similarly, is a very suitable material of which to form the cells for storing honey, as it does not become soft or soppy by the action of the water in the honey.

The chief proximate components of the waxes are: (1) esters of the fatty acids with alcohols containing a high number of carbon atoms; (2) esters of fatty acids with glycerol; (3) free fatty acids; (4) free alcohols containing a high number of carbon atoms; (5) hydrocarbons. With respect to the formulae of compounds containing a high number of carbon atoms, it should be borne in mind that a CH_2 more or less makes such a small difference in the percentage com-

position that the exact formula cannot be settled by a carbon and hydrogen determination, and consequently authors differ somewhat in the formulae they assign to the components of the waxes; such formulae must therefore be regarded as scarcely fixed yet. Another point to be remembered is that authors have sometimes been careless, in that they have stated that substances found in the products of saponification of a wax were present in the wax; thus it has been stated that beeswax contains myricyl (melissyl) alcohol and ceryl alcohol, when the experiments only showed that these were found after saponification. There was no evidence to show that the free alcohols were present, and no doubt those found came from esters in the beeswax.

The waxes, like most natural products, are mixtures of several components, and the isolation of these is a difficult and lengthy task, which has been attempted by comparatively few investigators. In consequence of this and in order to meet the requirements of commerce, it is customary when examining samples of the waxes to determine what may be called their *analytical values*, and from the results to infer their quality and freedom from adulterations. These values are also called the *characteristics* of the waxes; they have been much studied and include the physical determinations of specific gravity, melting point and sometimes refractive index, and also certain chemical determinations, which are explained below under the heading 'Beeswax.'

It has been observed that Japan wax has the peculiarity of showing a lower specific gravity and a lower melting-point when it has recently solidified after having been melted, than when some time has elapsed since solidifying. Other waxes probably possess similar peculiarities.

Text-Books.—Benedikt-Ulzer, *Analyse der Fette und Wacharten*, Fünfte Auflage, 1908. Leukowitsch und Warburton, *Chemical Technology and Analysis of Oils, Fats and Waxes*, 6th ed. 3 vols. 1921-23. Wolff, *Die Lösungsmittel der Fette, Öle, Wachse und Harze*, 1922.

Arjun wax (*White insect wax of India*). About the year 1788 a wax produced by an insect was noticed in Madras by Dr. James Anderson (Correspondence, 1788-1791) and was called by him *White Lac*. It was thought that it might resemble the Insect wax of China, but it is distinctly different. Attention has been drawn to it from time to time, but it seems never to have been utilised. The insect producing it was first named *Coccus ceriferus*, and later *Cero-plastes ceriferus*; it has been found on the arjun or kowa tree, on peepul, mango, tea bushes, and on other trees. The crude wax occurs on the twigs in small mounds of a dull buff colour; it contains some moisture and black matter from which it can be freed by melting and straining. When thus purified it is yellow like beeswax, and hard and brittle like resin. It is partially soluble in cold alcohol, and nearly all of it dissolves in boiling alcohol; when the solution cools it becomes white and opaque. In warm ether it dissolves readily, but not completely. In hot oil of turpentine it dissolves readily, but the liquid becomes white and opaque on cooling. In benzine it is easily soluble with the exception of a little brownish matter. Carbon disulphide dissolves it only partially.

Pearson (Phil. Trans. 1794, p. 383) examined the wax from Madras and found that it melted in water at 83°. He made candles of it, but found that they smoked and gave a resinous odour.

Moore (J. Agric. Hort. Soc. of India, 1874-78, 5, 78) reported on some from Chota Nagpur, that one specimen contained 11 p.c. of moisture, another 13 p.c.; that it melted at 55°; that (probably after drying and melting) the specific gravity was 1.04, and the composition corresponded to the formula $C_{11}H_{20}O$.

Holland (Indian Museum Notes, 1891-93, 2, 93) reported on some from the Central Provinces, that it (the crude material apparently) melted at 60°, and had a specific gravity of 1.04 at 29°.

Balanophore wax occurs in the parenchymatous cells of various species of Balanophoræ. These are small parasitic plants growing on the roots of various other plants and are found in abundance in Java. They are so rich in wax that they burn with a bright light, and the natives prepare candles by pounding the plants to a paste and coating thin strips of bamboo with this. The wax was named *balanophorin* by Göppert in Nova Acta Acad. Cæs. Leopoldino Carolinæ Nat. Curiosorum, 1841, 18 Suppl. 229, where a botanical account of the plants is given. The wax was examined by Poleck (*ibid.* 1847, 22, 117), who found that it was very soluble in ether and also that it dissolved when gently warmed with concentrated sulphuric acid and was precipitated again by dilution. It was examined more recently by Simon (Sitz. Ber. Kaiserl. Akad. Wissenschaften, Wien, 1910, 119 II. b, 1161). Air-dried slices of the plants (the latter had been preserved in alcohol) were reduced to a coarse powder and extracted with hot ether; they yielded about 65 p.c. of crude wax which, when melted and filtered (this took 4 months to accomplish), gave a honey-yellow wax, brittle when cold, but becoming soft when warmed in the hands and capable of being drawn out in fine threads. One part required about 140 parts of 95 p.c. alcohol for its solution, and of the product of this purification one part required about 50 parts of acetone for its solution. Balanophorin was thus obtained as a white amorphous powder. After further purification it was found to melt at 56°-57° to a colourless liquid resembling glycerin, which slowly solidified to a white wax. By analysis it was found to have a composition corresponding to $(C_{11}H_{20}O)_n$, just as Poleck had found. It gave no acid value nor saponification value. When strongly heated no acrolein was given off. Simon succeeded in decomposing it by distillation in a partial vacuum containing carbon dioxide, and also by fusion with potassium hydroxide, and in both cases obtained palmitic acid as a product. An account of other products was to be published later.

Langsdorffia hypogæa, another of the Balanophoræ, which is found near Bogota, in Colombia, yields large quantities of wax, and the stems are sold in the markets and used as candles on saints' days (Hooker, Trans. Linn. Soc. 1859 22, 41). This wax does not seem to have been chemically examined yet.

Beeswax is produced by the common bee *Apis mellifica*, and also by some allied species;

it is not collected from the flowers by the bee, but is the secretion of certain organs situated on the underside of the abdomen of the neuter or working bees, and is used by them in forming the cells of the honeycomb. They are said to consume about 10 lbs. of honey in order to secrete 1 lb. of wax. To obtain the wax the honey is allowed to run out from the comb, which is then pressed to separate as much honey as possible. The adhering honey and other impurities are next removed by melting the mass in hot water; the melted wax floats on the surface, and is strained to remove dead bees and brood. The residue is put in layers with straw, and is pressed to obtain more wax, the straw acting as a filter; this product is known as 'press wax.' The mass then remaining is sometimes extracted with benzine to obtain still more wax, the product being 'extraction wax.' The 'extraction wax' is apt to be impure from the use of artificial comb, and also from substances being extracted from the dead bees and straw; further, wax compositions and adulterated beeswax are also sold under the name of 'extraction wax' (Hirschel, Chem. Zeit. 1904, 28, 212). A common practice is to pare off the capping of the honey cells and then place the comb in a centrifugal machine, which removes the honey and leaves the comb undamaged, so that it can be replaced in the hive to be refilled by the bees, and thus save the honey that they would use to produce fresh wax. In this system the capping only is melted down for wax. Impurities may be introduced into beeswax by the use of artificial combs and foundations for combs made of materials other than beeswax. These are employed to save the honey which the bees would consume in making the wax.

Beeswax is yellow in colour and varies in tint, according to the materials employed by the bees and the care taken in its preparation; sometimes it is brownish, reddish, or greenish. It has a pleasant honey-like smell, which is made more apparent by warmth. When cold it is brittle; at ordinary temperatures it is tenacious; its fracture is dry and granular.

Solubility.—It is insoluble in water. Carbon tetrachloride is said to be the best solvent. Other solvents are: chloroform, carbon disulphide, tetralin (tetrahydronaphthalene), hexanil (hexahydrophenol), benzene, benzine, oil of turpentine, ether (not a very good solvent). The solvent is to be used hot, and in the case of some or all of these, a portion of the beeswax separates on cooling.

As regards ether, Buchner (Chem. Zeit. 1907, 31, 570) allowed beeswax to soak in ether at the ordinary temperature for some time, then filtered the resulting homogeneous paste, and washed it with ether; after getting rid of the ether he obtained from the filtrate 30 p.c. of a fairly soft, deep yellow mass, and from the insoluble residue 70 p.c. of a bright brownish wax considerably harder than the original wax. The soluble portion had an acid value of 40 and a saponification value of 83.8, whilst the insoluble portion had an acid value of 11.6 and a saponification value of 99.1; thus the part that dissolves is richer in acid and colouring matter and poorer in ester than the undissolved part.

Buchner (Chem. Zeit. 1918, 42, 373) also describes the difference in analytical values of

wax obtained from press-residues by using different solvents, namely, benzine, chloroform, and carbon tetrachloride. The esters appeared to be less easily dissolved than the other components, so that light benzine removed less of them than the other solvents, and the extraction wax, when light benzine was used, appeared abnormal.

Cold alcohol dissolves scarcely any; boiling alcohol dissolves a good deal (about 15 p.c. reckoning from the acid value), leaving an undissolved residue from which something is dissolved every time the treatment with boiling alcohol is repeated. All except about 2 p.c. is deposited when the alcohol cools.

Analytical values.—The creation of a systematic plan for examining samples of beeswax is due to Becker, Hohner, and Hübl. Becker (Dingl. poly. J. 1879, 234, 79), following Kottstorfer's plan for butter (Zeitsch. anal. Chem. 1879, 18, 199), determined the saponification value. Hohner (Analyst, 1883, 8, 16) determined the amount of potassium hydroxide required to neutralise the free acid and that required to saponify the whole wax; but he expressed his results in terms of cerotic acid and myricin. Hübl (Dingl. poly. J. 1883, 249, 338) prescribed the determination of the acid value, the ester value, the ratio value, and later for fats and oils (*ibid.* 1884, 253, 281) of the iodine value. The meaning of these terms may be briefly explained as follows:—

Acid value.—This is the number of milligrams of potassium hydroxide required to neutralise the free acids in one gram of the sample.

Saponification value.—When an oil, fat, or wax is boiled with alcoholic solution of potassium hydroxide, not only is the free acid neutralised, but the esters of the various acids are decomposed, potassium taking the place of the alcoholic radicles and forming salts (soaps) with the acids and the alcoholic radicles forming the corresponding alcohols. The number of milligrams of potassium hydroxide used in effecting these two actions for one gram of sample is called the *saponification value*.

Ester value.—If the acid value is deducted from the saponification value the remainder represents the number of milligrams of potassium hydroxide that has been used in decomposing the esters, and is called the *ester value*. Esters were formerly known as compound ethers, so the term *ether value* is sometimes found instead of *ester value*.

Ratio value.—If the ester value is divided by the acid value, the quotient is called the *ratio value*. It is useful in deciding on the purity of a sample.

Iodine value.—In most cases the oils, fats, and waxes contain unsaturated compounds; these when treated with solution of iodine and mercuric chloride under prescribed conditions combine with a certain amount of iodine. The percentage of iodine thus taken up is called the *iodine value*; it is a measure of the amount of unsaturated compounds in the sample. It differs from the other values in being a percentage and not a number of milligrams.

Total acid number.—Benedikt and Mangold (Chem. Zeit. 1891, 15, 474) proposed a determination of what they called the *total acid number*, but it has not come into general use.

Instead of 'value' the term 'number' is often used for the above results.

Although these values are a useful guide in judging the purity of a sample, they are not infallible, since it has been found possible, by a judicious mixture of ingredients, to prepare composition waxes which will give the correct analytical values for a pure beeswax.

Buchner value.—To examine samples of beeswax containing such composition waxes, Buchner (Chem. Zeit. 1895, 19, 1422, corrected by Kissling, *ibid.* p. 1682, and improved by Berg, *ibid.* 1903, 27, 753 and 754, and in Benedikt-Ulzer's Anal. Fette u. Wachsarten, 1908, p. 1095) devised a determination giving what is known as the *Buchner value*. The sample is boiled with alcohol, and then after 12 hours the acidity of the liquid is determined.

Weinwurm's test.—This is a test described by Weinwurm in Chem. Zeit. 1897, 21, 519, to detect paraffin or cerosin in beeswax. It uses glycerol and is useful, but not always reliable; see various papers in the bibliography and Benedikt-Ulzer, Anal. Fette u. Wachsarten, 5th ed. 1908, p. 1109.

Long tables giving the recorded analytical values of ordinary yellow beeswax are to be found in the text-books of Benedikt-Ulzer and of Lewkowitsch and Warburton; and Buchner in Zeitsch. öffentl. Chem. 1912, 18, 90, gave the values of some abnormal waxes. Berg (Chem. Zeit. 1903, 27, 752) gives a long table of the values of various waxes. They may be summarised as follows. Some errors have been corrected by the original sources, and 'press wax' and 'extraction wax' are excluded.

	Commonly occurring values lie between	Extreme values are	
		Minimum	Maximum
Specific gravity at 15°.	0.958 to 0.967	0.949 F. (0.941 L.)	0.972 Bt.
Melting-point	62.5° „ 66.5°	61° Bt. (60.5° L.)	68.5° Bg.
Acid value	17 „ 22	15.6 I.L.	25.7 Bch.
Ester value	70 „ 82	60.8 Bch.	84.9 Bg.
Saponification value . .	90 „ 103	80.8 Bch.	106.5 Bg.
Ratio value	3.2 „ 4.3	2.38 Bch.	5.0 I.L.
Buchner value	1.5 „ 6.1	1.1 M.	7.4 Bg.
Iodine value	6 „ 13	5.6 Bg.	17.12 Bg.

- L.—*Lidov*. Russian commercial samples, but it is not clear whether adulterated samples were excluded and in the sp.gr. the temperature is not stated, Chem. Zeit. Repert. 1905, 29, 278, from Westnik shirow. weschtsch, 1905, 6, 89.
- M.—*Mastbaum*. Portuguese beeswax, Zeitsch. angew. Chem. 1903, 16, 647.

Detailed directions for ascertaining the analytical values, for performing tests, and for interpreting the results will be found in the text-books and in the original papers; they have been subjects of much controversy especially those for the saponification value, since many of the waxes are not so readily saponified as the fats.

In deciding on the purity or otherwise of a sample, all the analytical values and the results of tests for impurities must be considered together. The text-books and various original papers and experience give guidance in forming an opinion.

Composition.—The composition of beeswax has received the attention of several investigators, and some account of the leading researches is given below.

Dr. J. F. John (Chem. Tabellen der Pflanzenanalysen, 1814, p. 42) separated beeswax by means of alcohol into a soluble and an insoluble portion. These he named *cerin* and *myricin* respectively, believing them to be the same substances that he had previously obtained from the wax of *Myrica cordifolia* from Cape Colony and had so named; thus making the common mistake of early investigators of identifying compounds from different sources on quite inadequate grounds. The *cerin* and *myricin* from beeswax and from *M. cordifolia*, however, must not now be regarded as identical. The latter wax seems not to have been examined recently and probably would be found to resemble myrtle wax in its composition. In Dr. John's time it was imagined that the number of compounds present in plants and animals was far fewer than are now known, and consequently compounds were believed to be identical if they agreed in a few simple properties. This belief has given rise to some misleading names.

Brodie (Phil. Trans. 1848, Pt. 1, 147; 1849, Pt. 1, 91), using Surrey and other beeswax, found two acids in the *cerin* or portion soluble in boiling alcohol, and named the most important of them with m.p. about 78° *cerotic acid*, giving it the formula $C_{21}H_{42}O_2$; he thought that the other acid was present in the wax in very small quantities; he estimated the wax to contain 25 p.c. of cerotic acid. In the *myricin*, or portion nearly insoluble in boiling alcohol, he found an ester of palmitic acid with a wax alcohol $C_{21}H_{42}O$ with m.p. 85°, which he named

melissin, no doubt from *melissa*, a bee. This alcohol is now called *myricyl alcohol*, or better, *melissyl alcohol*, since myricyl is a misleading name, arising from Dr. John's mistake, and very probably there is no myricyl present in the waxes of the *Myrica* group. Brodie also found in beeswax indications of other substances.

Very thorough investigations to find the components of beeswax were made by Nafziger (Annalen, 1884, 224, 225) and Schwalb (*ibid.* 1886, 235, 106); they used Württemberg country yellow wax and employed long series of fractionations. In the part soluble in hot alcohol, the *cerin*, Nafziger found principally cerotic acid with m.p. 78°, for which he favoured the formula $C_{21}H_{42}O_2$, or perhaps $C_{21}H_{40}O_2$; he found also some melissic acid $C_{20}H_{40}O_2$ with m.p. 89°–90°, and another acid of m.p. 75°–76° in small quantity. The ester portion left undissolved by the hot alcohol, the *myricin*, was saponified, and the product was extracted with hot petroleum ether to dissolve out wax alcohols, &c., thus leaving sodium salts of the fatty acids. From these latter he obtained palmitic acid $C_{16}H_{32}O_2$ with m.p. 61·5°, and satisfied himself that they included no salts of other higher fatty acids such as cerotic acid or melissic acid. Consequently no esters of such acids are present in the *myricin*, although cerotic and melissic acid are present in the wax in the free state and are found in the *cerin*. As regards acids of the oleic series: from the mother liquor of the *cerin* and from a certain mother liquor obtained in the examination of the *myricin*, he obtained similar yellow acid syrups having the characteristic odour of beeswax. These he believed to contain mixtures of acids of the oleic series, the odour being due either to these acids or to some special substance mixed with them. Thus these acids are present both free and as esters.

Schwalb completed Nafziger's work by examining the substances extracted by petroleum ether from the saponified *myricin* and so containing the wax alcohols which had existed as esters in the original wax. In this extract he found not only wax alcohols, but hydrocarbons; the presence of which in beeswax he was the first to discover. He isolated two which he believed to be normal heptacosane $C_{27}H_{56}$ with m.p. 60·5° and normal hentriacontane $C_{31}H_{64}$ with m.p. 68°; he also obtained a soft vaseline-like mass and thinks that other lower paraffins were present. He estimated the amount of the above two in beeswax (not the total hydrocarbons) to be about 5 to 6 p.c. As regards the alcohols produced by the saponification of the *myricin*, he found melissyl alcohol with m.p. 85°–85·5° and from it prepared the corresponding melissic acid with m.p. 88·5°–89°. He favoured the formula $C_{21}H_{42}O$ for the alcohol and $C_{21}H_{42}O_2$ for the acid. He also found evidence of the presence of lower alcohols in the saponification products, so to identify them he converted the mixture containing them into the corresponding acids and drew the conclusion that one was ceryl alcohol $C_{26}H_{54}O$ or $C_{27}H_{56}O$, convertible into cerotic acid by heating with soda lime and that another was $C_{25}H_{50}O$ or $C_{26}H_{52}O$. (These alcohols, doubtless, were not present free in the wax, but were produced by the saponification of their esters with palmitic acid.)

Marie (Ann. Chim. 1896 [7], 7, 145) made a close examination of the product regarded by Brodie as cerotic acid. He found that fractional solution in methyl alcohol was a much better method of separation than fractional precipitation or fractional crystallisation, and that it effected separation into pure cerotic acid and a much larger proportion of melissic acid than had previously been believed to be present. He regarded cerotic acid as being $C_{25}H_{50}O_2$ or $C_{26}H_{52}O_2$ with m.p. 77.5° , the evidence pointing to the first of these formulæ; and melissic acid as being $C_{20}H_{40}O_2$ with m.p. 90° . He obtained from beeswax about 15 p.c. of the pure mixed acids, and in this he found 30–40 p.c. of melissic acid. As regards these percentages, it should be noted that in extracting the beeswax with boiling alcohol to obtain the free cerotic and melissic acids a certain amount of myricin (melissyl palmitate, &c.) dissolves too. In the treatment adopted by Marie, namely, heating the crude mixed acids with potash-lime and potash, the alcohol radicles of the myricin are converted into melissic and cerotic acids, and these are included in his percentages, although they were not present free in the beeswax. What proportion they amounted to is not clearly stated; perhaps it was not large. His object was rather to get cerotic acid than to estimate its amount in beeswax.

Schalkef (Ber. 1876, 9, 278, and 1888; 1879, 12, 696, from Russian Phys. Chem. Soc.) thinks that cerotic acid, melissic acid, and melisin are mixtures of several substances and that in cerotic acid he found an acid with m.p. 91° and formula $C_{24}H_{48}O_2$. Lipp and Casimir (J. pr. Chem. 1919, 99, 263) found in Ghedda wax an acid with this formula, but with m.p. 94.5° – 95° .

Heiduschka and Gareis (J. pr. Chem. 1919, 99, 293) have studied the question of the formulæ for melissyl alcohol and melissic acid obtained from beeswax, and of the formulæ for the similar alcohol and acid obtained from carnaüba wax. They find that the products obtained from carnaüba wax have the formulæ $C_{20}H_{41}OH$ and $C_{20}H_{40}O_2$, whilst those from beeswax contain CH_2 more and are $C_{21}H_{43}OH$ and $C_{21}H_{42}O_2$. They succeeded in preparing from the carnaüba wax alcohol the acid with an added carbon atom, and found that its lead salt was identical with that of beeswax-melissic acid. Analyses of a number of compounds that they prepared also supported these views.

The question of the total amount of hydrocarbons in beeswax can hardly be considered as settled yet. In order to determine it A. and P. Buisine (Bull. Soc. chim. 1890, [3] 3, 872 and 1891, 5, 656), using Dumas and Stas's reaction (Annalen, 1840, 35, 129), heated beeswax with potash and potash lime to 250° . In this way potassium salts of the acids are formed and the alcoholic radicles in the esters are converted into salts of the corresponding acids with evolution of hydrogen; these salts remain undissolved when the product is extracted with ether or petroleum ether, whilst the hydrocarbons go into solution. They found 12.5–14.5 p.c. and that some were unsaturated as the hydrocarbon mixture absorbed 22 p.c. of iodine. Ahrens and Hett (J. Soc. Chem. Ind. 1899, 18, 591, from Zeitsch. öffentl. Chem. 5, 91), using Buisine's method, found from 12.7 to 17.5 p.c.

in different kinds of wax. Ryan and Dillon (Sci. Proc. Roy. Dublin Soc. 1916, 15, 107) found, however, that the product, supposed to be nothing but hydrocarbons, obtained from beeswax by a series of treatments, including Dumas and Stas's reaction, really contained a little oxygen; this amounted on an average to 0.8 p.c. It therefore seems that Buisine's method gives results which are too high. Ryan and Dillon suggest that some primary alcohol may be present in the product and also some secondary or tertiary alcohols; for they found that secondary and tertiary alcohols when heated with potash-lime evolve no hydrogen, and that primary alcohols do not evolve the full theoretical amount. The method thus requires further study.

The hydrocarbon, *melene*, found by Fictet and Bouvier (J. 1915, 604) in coal, in vacuum-tar, in Galician paraffin, and in the distillation products of beeswax, was assumed to be a solid naphthene, $C_{20}H_{40}$. J. Marcusson and F. Büttger (Ber. 1924, 57, 633) have now found that Indian paraffin wax, which melts at 60° – 60° , consists very largely of *melene*. The hydrocarbon can be readily isolated by crystallisation from benzene and then from benzine. It melts, when pure, at 62° – 63° , has $d_{20}^{25} 0.7913$; $d_{20}^{25} 0.9037$; $n_D^{20} = 1.4228$. Its composition corresponds to $C_{20}H_{40}$, and on oxidation with strong hot nitric acid, it gives a mixture of aliphatic acids, whereas naphthenes, under similar conditions, give nitro-compounds. Further, by catalytic oxidation with air in presence of manganese dioxide, *melene* yields solid fatty acids, whilst naphthenes yield polynaphthemic acids; and *melene* is slowly assimilated at 30° by *Bacterium aliphaticum*, which is incapable of attacking naphthenes. *Melene* is therefore a paraffin and not a naphthene (J. Soc. Chem. Ind. 1924, 43, B 457; cf. Funcke, Arch. Pharm. 1921, 259, 93).

In order to discover the cause of the difficulty experienced in saponifying beeswax completely Berg (Chem. Zeit. 1908, 32, 777) investigated the substances, amounting to about 2 p.c., that remain in solution after boiling beeswax in alcohol and allowing the liquid to cool, thus eliminating the crude cerotic acid and myricin. By evaporating the solution and extracting the residue thus obtained with ice-cold petroleum ether, he first separated as insoluble 0.44 p.c. of a brown semi-fluid mass having an intense beeswax odour. In the part that dissolved he found indications of various acids and then cholesterol esters, discovered by the colour test; he believes that 0.6 p.c. of these are present in beeswax, and probably considerably more. Such esters are difficult to saponify and have high saponification values. He saponified them and found cholesterols and several acids which seemed to be acetic, butyric, valeric, and others which were not volatile on the water bath, and included one that possessed the beeswax odour and was unsaturated, as its lead salt was soluble in ether. He did not succeed in making any ultimate analyses; but his work shows what a large number of compounds are contained in beeswax in minute proportions. He also examined in the same way a white wax bleached by permanganate.

Summing up the results of the various re-

searches, it appears that ordinary beeswax is composed chiefly of melissyl palmitate $C_{15}H_{31} \cdot C_{15}H_{31}O_2$, with some ceryl palmitate $C_{15}H_{31} \cdot C_{21}H_{43}O_2$, and some palmitate of the radicle $C_{15}H_{31}$; these are contained in the part known as myricin, which is very nearly insoluble in boiling alcohol. In the part known as cerin, which is soluble in boiling alcohol, there are present free acids amounting when purified to about 15 p.c. of the beeswax, chiefly cerotic acid. According to Mario, crude cerotic acid contains about 60 to 70 p.c. of cerotic acid $C_{26}H_{52}O_2$, and about 30 to 40 p.c. of melissic acid; but owing to the method he used, some of these acids may have come from decomposition of some of the myricin. There are also indications of the presence of another acid. Hydrocarbons are also present, namely, normal heptacosane $C_{27}H_{56}$, and normal hentriacontane $C_{31}H_{64}$, together amounting to 5 to 6 p.c., and in addition a soft vaseline-like mass has been separated.

Gascard and Damoy (Compt. rend. 1923, 177, 1222, 1442) state that after saponification they have obtained from beeswax the following compounds: (1) Neocerotic acid $C_{26}H_{52}O_2$ (m.p. 77.8°), the same acid that Mario described as having m.p. 77.8° and called cerotic acid. It has the same formula as Carius's hyaenic acid, but they consider that that was not a pure compound. (2) Cerotic acid $C_{27}H_{54}O_2$ (m.p. 82.5°), identical with that obtained from Chinese insect wax, and apparently identical with the acid that Tropsch and Kreutzer (Brennstoff-Chemie, 1922, 3, 49, 177) obtained from montan wax and named carbocerinic acid. (3) Montanic acid $C_{28}H_{56}O_2$ (m.p. 86.8°), apparently identical with the acid that Tropsch and Kreutzer (l.c.) obtained from montan wax and called montanic acid. (4) Melissic acid $C_{31}H_{62}O_2$ (m.p. 90°). They suggest that perhaps the acid that Brodie obtained from myricin is really not palmitic acid $C_{16}H_{32}O_2$, but one with an uneven number of carbon atoms. (5) Neoceryl alcohol $C_{26}H_{52}O$ (m.p. 75.5°). (6) Ceryl alcohol $C_{27}H_{54}O$ (m.p. 80°), identical with that from Chinese insect wax. (7) Montanyl alcohol $C_{28}H_{56}O$ (m.p. 84°). (8) Myricyl [melissyl] alcohol $C_{31}H_{64}O$ (m.p. 87°). The ceryl and melissyl alcohols were the most abundant of the alcohols. (9) Pentaacosane $C_{25}H_{50}$ (m.p. $54^\circ-54.5^\circ$). (10) Heptacosane $C_{27}H_{54}$ (m.p. $59.2^\circ-59.5^\circ$). (11) Nonacosane $C_{29}H_{58}$ (m.p. 63.5°). (12) Hentriacontane $C_{31}H_{62}$ (m.p. $68.4^\circ-69^\circ$).

Indications have been found of many minor constituents which have not yet been fully identified: (1) The yellow colouring matter which is very soluble in alcohol. (2) The substances to which the characteristic odour of beeswax is due. (3) Unsaturated acids (their lead salts being soluble in ether), both free and as esters; the odour seems to be associated with these. (4) Various other acids. (5) Cholesterols combined as esters, perhaps with acetic, butyric, valeric, and non-volatile acids. These cholesterol esters amount to at least 0.6 p.c. of the beeswax and very probably more, and perhaps some cholesterols are also present free. (6) It has been suggested that the difficult saponification of beeswax is due to the presence of lactones as well as to the cholesterol esters, since carnauba wax is known to yield a lactone. (7) Buchner (Zeitsch. öffentl. Chem. 1910, 16, 131) says that traces of

glycerides are nearly always present in beeswaxes.

It must be remembered that a substance like beeswax is not of constant composition and that there are many circumstances likely to cause variations such as the breed of the bee and the weather of the year it was produced in. Further, Reid (J. Soc. Chem. Ind. 1915, 34, 462) points out that usually in melting the comb some of the propolis is absorbed by the wax, and that the wax from old pollen-clogged combs is different from that from new combs.

Foreign varieties of beeswax.—In addition to wax resembling European beeswax fairly closely, varieties giving very different analytical values are imported into Europe; they are products of various species of bees other than *Apis mellifica*. About 1896, samples of Indian beeswax were appearing in Germany under the name of *Ghedda wax* and were examined by Buchner; it turned out later that they were products from *Apis dorsata*, *A. indica*, and *A. florea*. He found that they gave values differing considerably from those of ordinary beeswax, although they resembled it in appearance. They were, however, brighter in colour, more plastic, and had a pleasant odour, which was especially noticeable on saponification. This Indian beeswax continued to come on the German market from Bombay. Buchner (Chem. Zeit. 1905, 29, 79) found that it was characterised by a low acid value, a high ester value, and a high ratio value; thus in 36 samples he found the acid value to range from 5.3 to 12.2, but only in four samples was it over 10. The ester value ranged from 75.2 to 111.5, the saponification value from 81.8 to 120.2, and the ratio value from 7.4 to 17.9. Wax of this description appears sometimes to have been called China wax, and may have come from Annam or French Cochinchina as well as from India. Buchner maintains that Ghedda wax is a true beeswax (Chem. Zeit. 1905, 29, 79 and 1906, 30, 529), so that the difference in its analytical values must be remembered when judging the purity of a beeswax.

Hooper (Agricultural Ledger of India, 1904, 11, 73) describes the species of bees found in India, and the wax and honey trade there. The wax is derived from *Apis dorsata*, *A. indica*, and *A. florea*, but chiefly from *A. dorsata*; *A. mellifica* does not occur there except as an importation. The wax from the combs of these three species seems to be substantially of the same composition. It differs from European beeswax in having a much lower acid value; in the case of 33 specimens from these three species the acid value ranged from 4.4 to 10.2, with an average of about 7, the ester value from 69.5 to 123.8, the saponification value from 75.6 to 130.5, and the Hübl iodine value from 4.8 to 11.4. The m.p. ranged from 60° to 68° . Some Indian waxes of unknown origin gave higher acid values and other values outside these limits. In the comb the upper part gives a clean white wax and the lower part a dirty and coloured substance; but as a rule these parts are not separated before melting. Turmeric is universally added to give the wax a golden yellow colour, as white wax is not appreciated in the native markets. In one district it is said that oil of *Sesamum indicum* is added.

Hooper (l.c. p. 79) also describes another kind

of beeswax produced in India and Burma by minute stingless bees of the *Melipona* or *Trigona* species, sometimes called mosquito bees or dammar bees. It is of a blackish colour and sticky consistency. In 8 specimens the acid value ranged from 16.1 to 22.9, the ester value from 55.2 to 128.3, the saponification value from 73.7 to 150, the iodine value from 30.2 to 49.6, and the m.p. from 66° to 76°.

Most probably the natives do not keep the *Melipona* wax separate, but mix it indiscriminately with the wax of the three *Apis* species.

Hooper describes (*ibid.* 1908 9, [3] 31, Abstract in J. Soc. Chem. Ind. 1909, 28, 664) *Pwé-nyet* (black wax of Burma) obtained from the nests of *Trigona laeviceps* and possibly from those of other dammar bees; it is not always black and seems to be more of a resin than a wax.

In the old records a wax called *Andaquies wax* is described as being collected by the Indians in New Grenada (now Colombia), especially by the Tamas tribe, which lives near the Rio Caquetá. It was probably the product of small *Melipona* bees. A sample was examined by Lewy (Ann. Chim. 1845, [3] 13, 453); after purifying it by treatment with boiling water he found that its m.p. was 77°, its sp.gr. at 0° was 0.917, and that it contained 81.66 p.c. of carbon and 13.55 p.c. of hydrogen. It was used locally for making candles for religious worship.

A black beeswax found in the Dutch Indies is described by Blits (Nederl. Tijdschr. Pharm. 10, 35, abstr. in J. Soc. Chem. Ind. 1898, 17, 468), and the wax of a South Brazilian bee, probably of the *Melipona* or *Trigona* species, is described by Gadamer and Hinderer (Arch. Pharm. 1917, 255, 425), who gives its composition as well as its analytical values.

Returning to the Ghedda wax, there is a long paper by Buchner and Fischer (Zeitsch. öffentl. Chem. 1913, 19, pp. 147, 170, and 188) on East Indian or Ghedda wax, and on so-called China wax, which gives 160 analyses by Buchner and 108 analyses by Schulten, of Calcutta. Further information about the beeswaxes of India and Eastern Asia is given by several papers of Fischer (*ibid.* for 1913 and 1914). Recently 23 samples of comb and beeswax from Bengal and Assam, collected under the supervision of District Officers, were examined at the Imperial Institute by Roberts and Islip (Analyst, 1922, 46, 246); they found that neither *Weinwurm's* test nor that of Salamon and Seaber could be relied on.

The composition of Ghedda wax or East Indian beeswax has been investigated by Lipp, with Kuhn, Kovács, and Casimir (J. pr. Chem. 1912, 86, 184; 1919, 99, 243, and 256). They found that the principal components are: one of the ceryl hydroxymargarates

ceryl margarate $C_{17}H_{33}C_{17}H_{33}O_2$, and ceryl palmitate $C_{16}H_{31}C_{17}H_{33}O_2$; together with roughly 7 p.c. of hydrocarbons, namely: heptacosane $C_{27}H_{54}$ (roughly 5 p.c.), hentriacontane $C_{31}H_{62}$ (roughly 2 p.c.), and indications of another hydrocarbon which they could not isolate. As in European beeswax, they found some free acids, but only in small proportions, namely, cerotic acid $C_{26}H_{50}O_2$ and an acid $C_{24}H_{48}O_2$, which they named *Ghedda acid*. Its m.p. was 94.5°-95°.

An acid with this formula and m.p. 91° was described by Schaltef (Ber. 1876, 9, 278, and 1888). These two acids are present chiefly in the free state and the other acids as ceryl esters. In the products of hydrolysis they found also, but only in small proportion, a different hydroxymargaric acid and traces of formic, acetic, and butyric acids and of a resinous substance.

White or bleached beeswax.—Most beeswax is bleached before use; bleached beeswax is harder, and candles made from it burn better than those made of yellow beeswax. The bleaching is effected by exposure to light and air or by chemical agents, or by both methods. Chemical agents do not bleach it so thoroughly as does light, so that when they are used a final bleaching by light is required to get the best results; they serve, however, to shorten the time taken in bleaching.

The wax is first purified by repeated meltings in hot water until it is no longer grey, and any remaining honey is removed. In doing this the grey underlayer is cut or scraped off from the cooled cake of wax, and is remelted with the next lot treated. If the water used is hard, it is stated (Cheshire, Bees and Bee-Keeping, p. 589) that the cerotic acid of the wax forms an insoluble calcium soap, appearing as a grey spongy material and that thus a waste of wax is occasioned. Rain-water or distilled water should therefore be used, or else the water should be acidified with sulphuric acid. The use of acidified water also checks the formation of emulsions, and is recommended for the various remeltings. Old and dirty combs should be soaked in cold water for some time before melting, as the dirt and cocoon skins when wet do not absorb and waste wax as they would if dry.

In order to expose as much surface as possible to the sun's rays, the wax is reduced to thin bands. The melted wax is poured into a box of metal plate, in the bottom of which are several narrow slits or holes. These are directly over a horizontal wooden roller revolving in a vessel containing cold water, which covers half the roller. The wax escapes from the slits in bands, which pass on to the revolving roller and solidify in the water in the form of thin ribbons. These ribbons are removed from the water, spread on canvas stretched over wooden frames, and exposed to the sun; they are sprinkled from time to time with water to keep them moist, and turned over to expose fresh surfaces to the sun. If the sunshine is very powerful, the heat may cause the ribbons to stick together; this can be avoided by watering, but not more than is necessary should be employed, as Heinz (Seifensieder Zeitung, 1913, 40, 1140) thinks that evaporating water vapour checks the oxidizing action of the air. The inner portion of the ribbon bleaches more slowly than the outer surface, so to accelerate the bleaching the partially bleached wax is remelted and again made into ribbons, so that new surfaces are exposed; this remelting, however, causes some loss. Wax from different sources bleaches with varying facility, and some varieties cannot be bleached, so samples should first be tried on a small scale.

The addition of a little oil of turpentine to the yellow wax before making it into ribbons reduces the time taken in bleaching, but in acid

by Heins to impart an unpleasant odour to the wax. Rectified oil of turpentine free from resin should be used. The bleaching effect of oil of turpentine was noticed by Ostermaier (Repert. f. d. Pharm. 1834, 48, 97). Sometimes a few p.c. of tallow are added to the wax to hasten the bleaching and to diminish brittleness, and this is considered allowable and is not counted as an adulteration.

After a longer or shorter period, depending on the intensity of the sunshine and the temperature, the bleaching is complete; it takes from 10 to 60 days. The wax is then once more melted in hot water, strained, and allowed to solidify in suitable shapes.

When chemical agents are used a mixture of potassium dichromate and sulphuric acid is said to be the best (Heinz, Seifensieder Zeitung, 1913, 40, 1140, 1169, and 1192). The wax is boiled with a solution containing 12 parts of potassium dichromate and 35 parts of sulphuric acid to 100 parts of water and wax. The green chromium compound produced by the reduction of the dichromate is removed by washing the wax with water containing 6-8 p.c. of lactic acid, or containing sulphuric acid. This process has been found effective even with some waxes that were considered unbleachable.

Potassium permanganate solution, followed by sulphurous acid has been tried, but the results were not very satisfactory. Other chemical agents that have been tried or recommended are the use of artificially made ozone, of hydrogen peroxide acidified with sulphuric acid, of barium peroxide of potassium chlorate with sulphuric acid, of a liquid prepared from bleaching powder and soda. The formation of chlorine compounds in the wax is objectionable, however, as hydrochloric acid is liberated when the wax is burnt. Whenever chemicals are used they should be thoroughly washed out of the wax when the bleaching is accomplished.

Another proposed way of decolorizing beeswax is by the use of agents that absorb the colouring matters, such as animal charcoal, fuller's earth, and the like.

The theory of bleaching and the effect of various methods and also the effect of the addition of a little tallow to the yellow wax have been studied by A. and P. Buisine (Compt. rend. 1891, 112, 738, and Bull. Soc. chim. 1890, [3] 4, 465); they found that light is necessary, since, in the dark, yellow wax is not bleached when kept in a current of air or of oxygen or of ozonised oxygen, whilst in sunlight it is bleached even when kept in carbon dioxide or nitrogen or in a vacuum, though much more slowly than in air. In oxygen it bleaches more rapidly than in air, and very rapidly in ozonised oxygen. They noticed that in air-bleaching the colour does not decrease uniformly, but that white spots are seen which increase in size. They think that the colouring matter undergoes total combustion and that the oxidation of the unsaturated hydrocarbons and unsaturated acids induce this combustion, and that is why the addition of tallow, which contains olein, helps the bleaching. Oil of turpentine acts in the same way because it undergoes oxidation. They think it probable that these substances when undergoing oxidation in the light give rise to ozone, and that this under the influence of light burns up the colour-

ing matter; it being known that oil of turpentine exposed to air and light produces ozone, and that tallow, whilst turning rancid, gives an odour like ozone. They found in most cases that the m.p., the acid value, and the saponification value are increased, and that the iodine value and the percentage of hydrocarbons are lowered; decolorizing by animal charcoal, however, caused little change in the values.

Berg (Chem. Zeit. 1902, 26, 605) also records many experiments on the subject; he finds that the acid value is raised and the ratio value consequently lowered, which should be borne in mind when examining a white wax for admixtures. It is not easy, however, to draw general conclusions from his results. In Chem. Zeit. 1903, 27, 754, and 1908, 32, 778, he again treats of white wax.

Medicus and Wellenstein (Zeitsch. Nahr. Genussm. 1902, 5, 1092) examined the bleaching action of potassium chromate and sulphuric acid; they found: (1) that the acid value and the saponification value were considerably increased, but that the ester value was unaltered; (2) that the m.p. was raised 1°; (3) that the characteristic odour of yellow wax was destroyed or volatilised; (4) that no stearic acid could be found by the Fehling-Röttger test either before or after bleaching; (5) that the ester value of some myricin prepared from yellow wax was only slightly increased by bleaching.

Bibliography.—A very full bibliography for the years 1848 to 1891 is given in the U.S. Dept. Agric. Div. Chem. Bull. 13, Pt. 6, 1892, with an account of the contents of many of the papers. An abstract of this is given in J. Soc. Chem. Ind. 1892, 11, 756. The following are papers of 1892 and after, with a few earlier ones. A. and P. Buisine (Bull. Soc. chim. 1890, [3] 3, 867), methods of examination, including determination of the hydrocarbons and of the hydrogen evolved by Dumas and Stas's reaction. Kossel, Obermüller, and Krüger (Zeitsch. Physiol. Chem. 1890, 14, 599; 1891, 15, 321; 1892, 16, 152), use of sodium alcoholate or of metallic sodium for saponifying. Antoushevich (J. Soc. Chem. Ind. 1891, 10, 1014, from J. Russ. Chem. Soc. 1891, 23, 223), analyses of Russian waxes and method of analysis. Forde (Consular Report No. 1304 for Morocco for 1892, p. 17), adulteration with low-class paraffin from candles. Röttger (Chem. Zeit. 1892, 16, 1837), methods of analysis, criticism of Benedikt and Mangold's method. Buchner (*ibid.* p. 1922), methods of analysis. Benedikt (*ibid.* p. 1923), defence of Benedikt and Mangold's method. Marie (Bull. Soc. chim. 1892 [3] 7, 111), bromoacetic acid. Gascard (J. Pharm. Chim. 1893, [5] 28, 49), myricyl (melissyl) alcohol from beeswax, carnauba wax and gum-lac, and its derivatives. Buchner (Chem. Zeit. 1893, 17, 918), criticism of Hübl's method, and some extra tests recommended. Köbler (J. Franklin Inst. 1894, 137, 58), detection of adulterants. Parry and Estcourt (Year Book of Pharm. 1893, 370 and Chem. and Druggist, 1894, 45, 645, and 693), adulterants and their detection. Kromer (Chem. Zeit. Repert. 1895, 19, 290, from Pharm. Zeitsch. Russl. 1895, 34, 629), composition of the oil obtained by the dry distillation of beeswax and used as a remedy. Buchner (Chem. Zeit. 1896, 19, 1422), artificial compositions giving the same

analytical values as beeswax and used as adulterants; method for roughly estimating the amount of adulterant by determining a value afterwards known as the Buchner number. (For some additional directions, see Benedikt-Ulzer's book, 5th ed. 1908, p. 1095.) Buchner's method of calculation was wrong, see the next paper. Kissling (*ibid.* p. 1682), correction of Buchner's method of calculation in the previous paper. Henriques (*Zeitsch. angew. Chem.* 1895, 721 and 1896, 221), method of finding the saponification value, using petrol-ether or for waxes petrol-benzin as the solvent, and saponifying in the cold with alcoholic sodium hydroxide solution. Marie (*Bull. Soc. chim.* 1894 [3] 11, 908 and *Ann. Chim.* 1896, [7] 7, 145-250), the latter is a long paper on cerotic and melissic acids from beeswax, on their separation from one another by fractional solution in methyl alcohol and on their derivatives. Ramboe (*Chem. Zeit.* 1896, 20, 1004), circumstances and processes favouring bleaching. Lugowsky (*J. Pharm. Chim.* 1897, [6] 5, 295, from *Pharm. Zeitsch. f. Russland*, 1896, 35, 839), detection of Japan wax and tallow in beeswax. Blarez (*Revue internat. des falsifications*, 1897, 10, 161), ceresinometer. Weinwurm (*Chem. Zeit.* 1897, 21, 519), Weinwurm's test for ceresin and paraffin, also his way of carrying out saponification; [but see the next paper]. [Note: Several authors say that Weinwurm's test is not trustworthy]. Henriques (*Chem. Rev. Fett. u. Harz-Ind.* 1897, 4, 195), a variation in Weinwurm's test [but see the next reference] and an objection to Weinwurm's way of saponifying, and also to the test being applicable for the detection of resin. Henriques (*Chem. Cent.* 1897, ii. 647, from *Zeitsch. öfentl. Chem.* 1897, 3, 274), a modification of Weinwurm's test. Henriques later stated that this modification was unreliable and warned against its use, see Lunge, *Chem. tech. Untersuchungsmethoden*, 1900, 4th. ed. vol. 3, p. 151. Dieterich (*Chem. Rev. Fett. u. Harz-Ind.* 1897, 4, 259), finds that Henriques' cold saponification gives lower values than Hübl's hot saponification. Henriques, in a note, says that he has not found this lowness. Dieterich (*Helfenberger Annalen*, 1897, 218), numerous analyses comparing cold with hot saponification. Buchner (*J. Soc. Chem. Ind.* 1898, 17, 383, from *Zeitsch. öfentl. Chem.* 1897, 3, 570), analyses of Indian waxes and of waxes called Chinese [probably incorrectly] giving values different from ordinary beeswax, and on the cold saponification method. Guyer (*Pharm. J.* 1897, 58, 308), iodine values of English beeswax. Woy (*Chem. Cent.* 1897, i. 565, from *Zeitsch. öfentl. Chem.* 1897, 3, 15), difficulty of saponifying overcome by using Müller's extractor. Beythien (*Chem. Rev. Fett. u. Harz-Ind.* 1898, 5, 16, from *Pharm. Centralhalle*, 1897, 38, 850), use of sodium ethylate for saponifying; also a comment by Henriques. Blits (*J. Soc. Chem. Ind.* 1898, 17, 468, from *Nederl. Tijdschr. Pharm.* 10, 35), black beeswax from the Dutch Indies. Werder (*Chem. Zeit.* 1898, 22, 38 and 59), use of refractometer for beeswax and other waxes with table of results. Dieterich (*ibid.* p. 729), a number of iodine values, and effect of various adulterants on the various analytical values, also on solubility in chloroform as a criterion. Henriques (*Zeitsch. anal. Chem.* 1898, 37, 699,

from *Zeitsch. öfentl. Chem.* 1898, 4, 416), duration for cold saponification. Kayser (*J. Soc. Chem. Ind.* 1899, 18, 152, from *Zeitsch. öfentl. Chem.* 1898, 4, 833), analytical values of Morocco beeswax. Funaro (*Chem. Cent.* 1899, ii. 404, from *L'Orosi*, 22, 109), analytical values of Italian beeswax and methods of finding adulterants. Ahrens and Hett (*Chem. Cent.* 1899, i. 952, from *Zeitsch. öfentl. Chem.* 1899, 5, 91), determination of hydrocarbons in beeswax and their amount. Lewkowsitch (*Analyst*, 1899, 24, 319), on the acetyl value. Charcheffsky (*Chem. Zeit.* 1899, 23, 597), electrical melting-point apparatus. Dluskki (*Chem. Zeit. Repert.* 1900, 24, 30, from *Farmazeft*, 1899, 7, 1307), finding ceresin and paraffin by Hübl's saponification, and on the wax got from dead bees. Werder (*Chem. Zeit.* 1900, 24, 967), time necessary for saponification and method of detecting adulterants. Dieterich (*ibid.* p. 994), time necessary for saponification. Eichhorn (*Zeitsch. anal. Chem.* 1900, 39, 640), use of amyl alcohol to surmount the difficulty in saponifying and to determine the acid value. Hett and Ahrens (*Zeitsch. angew. Chem.* 1900, 152), directions for analysis and results from beeswax from various countries. Buchner (*Oil World*, 1900, 1, 36), particulars and uses.

In this Century.—Buchner (*Chem. Zeit.* 1901 25, 21 and 37), methods for determining analytical values and for detecting adulterants; results for ordinary beeswax, Indian Ghedda wax, African beeswax and bleached wax. Greshoff and Sack (*Rec. trav. chim.* 1901, 20, 75), products of the dry distillation of beeswax. Jean (*Ann. Chim. anal.* 1901, 6, 447), examination for resin and other adulterants. Marpmann (*Chem. Rev. Fett. u. Harz-Ind.* 1901, 8, 65), refractive indexes as a means of examining waxes. Davis (*J. Amor. Chem. Soc.* 1901, 23, 487), method to avoid spitting when estimating water. Berg (*Chem. Zeit.* 1902, 26, 310), rye-meal found in a sample. Dieterich (*ibid.* p. 554), adulterated Turkish samples. Berg (*ibid.* p. 605), effect of bleaching on the analytical values. Medicus and Wellenstein (*Zeitsch. Nahr. Genussm.* 1902, 5, 1092), effect of bleaching by chromate on the analytical values and on the components of beeswax. Mastbaum (*Zeitsch. angew. Chem.* 1902, 15, 920), a specific gravity bottle for use in boiling water. Reid (*J. Soc. Arts*, 1903, 51, 522), separating the honey from the comb. Berg (*Chem. Zeit.* 1903, 27, 752), analytical values of numerous samples and methods employed. Dieterich (*ibid.* p. 808), controversy on Berg's paper, on time necessary for iodine value determination, and on Storck's test for colophony. Berg (*ibid.* p. 986), a reply to Dieterich. Mastbaum (*Zeitsch. angew. Chem.* 1903, 16, 647), beeswax of Portugal and its colonies, statistics, analytical methods and results. Hirschel (*Chem. Zeit.* 1904, 28, 213), preparation and analytical values of 'extraction beeswax.' Löwy (*ibid.* p. 348), criticism of the preceding paper. Hirschel (*ibid.* p. 480), reply. Lemaire (*J. Soc. Chem. Ind.* 1904, 23, 840, from *Bull. Soc. Pharm. de Bordeaux*, 1904, 44, 182), detection of artificial colouring matter. Hooper (*Agric. Ledger of India*, 1904, *Entom. Chem. 1911, 50, 692), on the same subject, and that ascarotida was perhaps used in the 15th century, to give a beeswax odour. Sundwik (Zeitsch. physiol. Chem. 1911, 72, 455), alcohols of psylla wax and of beeswax compared. Winkler (Zeitsch. angew. Chem. 1911, 24, 636), use of propyl alcohol solutions for finding saponification and acid values. Wichmann (J. Chem. Soc. 1911, ii, 550, from Pharm. Zentralhalle, 1911, 52, 363), saponifying by heat and pressure. Imp. Inst. Bull. 1911, 9, 236, analytical values of various African samples; a caution about Weinwurm's test. Buchner (Zeitsch. öfentl. Chem. 1911, 17, 225), behaviour of ordinary and foreign samples, pure and adulterated, with certain extra tests; on Weinwurm's test; on glycerides in pure beeswax. Buchner (*ibid.* p. 311), a mistake in Deutsches Arzneibuch of 1910. Buchner (*ibid.* 1912, 18, 90), on some abnormal samples. By an application of Denigès methylglyoxal test (Bull. Soc. Pharm. Bordeaux, 1896), P. Bourcet (Bull. Soc. chim. 1924, 35, 421) has shown that pure beeswax gives no glycerol on saponification. A positive reaction therefore indicates adulteration. White beeswax often gives a positive test for glycerol, owing to the addition of tallow to the wax before bleaching. The test is carried out as follows: 2-3 gm. of the wax are saponified with 10-15 c.c. of potassium hydroxide solution for 1 hour. After dilution with 15 c.c. of water, the mixture is slowly acidified with dilute sulphuric acid (1:4) and filtered; 2 c.c. of the filtrate are treated with 20 c.c. of saturated bromine water till colourless, and 2 c.c. of this solution are treated with 0.1 c.c. of alcoholic solution of codeine and 5 c.c. of pure sulphuric acid (d. 1.84). After shaking and heating on a boiling water bath for 2 minutes, a fine greenish-blue coloration develops if glycerol is present; 1 p.c. of a glyceride can easily be detected in beeswax by this test (J. Soc. Chem. Ind. 1924, 43, B. 431). Lipp and Kuhn (J. pr. Chem. 1912, 86, 184), composition of Indian (Ghedda) beeswax. Mastbaum (Chem. Rev. Fett-u. Harz-Ind. 1912, 19, 232 and 260), beeswax of Portugal and its colonies; method of examining. Prettnner (Prometheus, 1912, 23, 341), origin, preparation, uses, and adulterants. Leys (J. Pharm. Candelilla wax is obtained from plants growing wild in great quantities in the dry and desert-like districts of northern Mexico and the southern parts of the United States; they are called 'candelilla' by the Mexicans. It is a recent addition to the waxes in commercial use, attention having been called to the wax on these plants by Sanders in 1905. *Euphorbia corollata* (Alcoocor), *E. antiophyllitica* (Zucc.), and *Pedicularis Peroviana* (Boiss.) have been given as the plants from which the wax is obtained.

It occurs as an excretion covering all parts of

the plant, except the roots. It can be obtained by boiling the plants with water and skimming off the layer of melted wax; the pieces of plant must be kept from rising by enclosing them in wire cloth or by tying them in bundles and weighting these down. In practice a little sulphuric acid is added to the water when first obtaining the wax, and also when remelting; its action is probably to prevent the formation of an emulsion. Another plan is to subject the plant in suitable containers to live steam, which melts off the wax, and this can be easily separated from the condensed water. It is said that this plan gives a better yield, but that the wax appears softer and contains more water than that obtained by simply boiling out the wax from the plant. The wax can be purified by remelting and straining off plant debris. The yield of wax is from 1 to 5 p.c. In 1918 there were about twenty-five factories producing the wax in the Monterey district.

The wax is hard and brittle, and can be broken down to a powder at low temperatures; when full of air bubbles and water it is opaque and greyish-yellow in colour, but if these are got rid of by melting it is dark brown and translucent. When heated it gives off an aromatic odour. It is only slightly soluble in alcohol, ether, acetone, chloroform, carbon disulphide, gasoline, and oil of turpentine when cold, but is readily soluble in all these when hot; a boiling mixture of three parts absolute alcohol and two parts of 90 p.c. benzene was found to be an excellent solvent. On cooling these solutions become pomade-like masses.

The analytical values that have been recorded vary widely; this may be due to the age of the plant, the time of year at which it was gathered, the mode of preparation, the presence of water in the sample examined, the method of analysis, or even to adulteration. The following are the lowest and highest values found in the literature of the wax: m.p. 65° to 92°; sp.gr. 0.936 to 0.998; acid value 0.03 to 24; saponification value 35 to 104; iodine value 5.2 to 57.6; unsaponifiable matter 65 to 91.2 p.c. There are also variable amounts of dirt, water, and ash. These analytical values vary so much that it may be well to add those of the following authors.

Sanders (Chem. Soc. Proc. 1911, 27, 250) states that a sample of wax prepared in January from plants collected in Coahuila was greenish-white, and contained a considerable proportion of water. When freed from this it was dark brown and gave the following values: m.p. 67.5°; sp.gr. 0.9850; acid value 14.39; saponification value 46.76; iodine value (Hübl) 16.60; unsaponifiable matter 77.00 p.c.; and hydrocarbons 48.60 p.c.; he found hentriacontane and melissyl alcohol (whether free or as ester is not stated).

Lüdecke (Seifensieder Zeit. 1912, 39, 829) gives as normal values: m.p. 68-70°; sp.gr. 0.950-0.990; acid value 13-18; saponification value 50-60; iodine value 15-20; unsaponifiable matter 65-75 p.c.; moisture 2 to 3 p.c.; and dirt 0 to 3 p.c.

Berg (Chem. Zeit. 1914, 38, 1162) gives for a grey crude wax: m.p. 80-88°; acid value 9.8; ester value 44.0; saponification value 53.6; and as the mean of two samples of brown wax: m.p. 68.5°; sp.gr. at 15°/15° 0.986; acid value

11.6; ester value 51.5; saponification value 65.1; iodine value (Wijs) 57.6 after 19 hours standing, 14.5 after 3 hours; unsaponifiable matter 67.5 p.c. Both Berg and Lüdecke used xylene when saponifying.

Composition.—Candelilla wax is remarkable among the waxes for the high proportion of hydrocarbons that it contains, but as in the case of its analytical values the results of investigations as to its composition are discordant. Sanders, in *Anal. Inst. Med. Nacional, Mexico*, for Oct. 1907, recorded the presence of hentriacontane (*J. Ind. Eng. Chem.* 1911, 3, 115). Fraps and Rather (*ibid.* 1910, 2, 454) found hentriacontane with m.p. 68°, and indications of another hydrocarbon with m.p. 85°, and of other substances.

Meyer and Soyka (*Monatsh.* 1913, 34, 1159) found that it contained resin amounting to 18 to 20 p.c., to this they attribute the acid value and the iodine value. They removed most of the resin by repeatedly boiling out the wax with alcohol, allowing to cool and then separating the alcoholic resin-solutions; they then removed from the residue all that ether would dissolve. In the soluble part, after removing the last traces of resin by the charring action of thionyl chloride, they found a hydrocarbon which they believe to be normal dotriacontane $C_{32}H_{66}$, with m.p. 71°, and in the insoluble part they found an oxylactone $C_{30}H_{58}O_2$, with m.p. 88° to 88.5°, identical or isomeric with the lactone of lanoceric acid. They sum up the composition as 18 to 20 p.c. of resin, 74 to 76 p.c. of dotriacontane, and 5 to 6 p.c. of the oxylactone.

Berg (*Chem. Zeit.* 1914, 38, 1162) found: (a and b) about 50 p.c. of two hydrocarbons, one with m.p. 68° and the other with m.p. 84°–85°; (c and d) about 10 p.c. of a semi-fluid mixture of two cholesterols, these were free in the wax, when acetylated they yielded acetates, one a white powder, nearly insoluble in alcohol, the other readily soluble in alcohol on warming; (e) a small quantity of a substance containing oxygen, with m.p. 88°–89°, it was fairly soluble in alcohol, could be acetylated, did not give any cholesterol reaction, and must have been present in the wax as an ester; (f) a very small quantity of a substance containing oxygen, melting with decomposition at 243°, it was readily soluble in alcohol, from which it crystallised in leaflets, it could not be acetylated, it gave a colour reaction with acetic anhydride and sulphuric acid, and may be an ester of a lupool-like cholesterol.

Buchner (*Chem. Zeit.* 1918, 42, 374) gives the composition as determined by Staempfli as: 50–53 p.c. of a hydrocarbon $C_{31}H_{64}$, with m.p. 68°; 25 p.c. of melissic acid $C_{31}H_{62}O_2$, present partly free and partly as a melissyl ester with m.p. 88°–90°; 10–14 p.c. of melissyl alcohol $C_{31}H_{64}O$, with m.p. 85° (whether free or as ester is not stated); 1 p.c. of another hydrocarbon, with m.p. 85°; traces of a phytosterol, with m.p. over 130°; and 10 p.c. of resinous matter; but none of the experimental evidence is given.

Uses.—Owing to its hardness it resembles carnauba wax. It is especially valuable in making shoe-creams and polishes, as it imparts to such preparations the power of producing a brighter lustre than any other wax. On the other hand, when mixed with paraffin wax it

has not nearly as great a hardening effect as carnauba wax, and it has little hardening action when mixed with soft wax compositions. For candle making it is considered inferior to carnauba wax, owing to its lower melting-point (given as 65°), and for phonograph records its suitability is considered small. The insulation of telephone cables is another suggested use.

Cape berry wax. Samples of this wax have been shown at exhibitions in London, and it is capable of being collected in quantities in Cape Colony, but it has not yet come into any extensive use. It is probably derived from one of the species of *Myrica* growing in South Africa, which include *M. quercifolia* (Linn.), *M. cordifolia* (Linn.), and *M. serrata* (Lam.); it is similar to myrtle berry wax in its general characters and in its physical and chemical properties, which were found to be: sp.gr. 0.874 at 99°; m.p. 40.5°; m.p. of the fatty acids 47.5°; mean molecular weight of the fatty acids 236.1; acid value 4.1; saponification value 211.1; iodine value 1.1. It yields a hard white soap, but does not seem to be suitable for candle making (*Imp. Inst. Bull.* 1906, 4, 300). The results of another examination are: sp.gr. 0.9893; m.p. 49°; refractive index at 80° 1.4364; acid value 2.5; saponification value 212.3; iodine value 2.03; unsaponifiable matter 2.51 p.c.; fatty acids 89.7 p.c.; m.p. of mixed fatty acids 48.5°; solidifying-point of these 46.5°; mean molecular weight of these 241.4; it was described as South African berry wax, and was pale greenish-grey with a granular fracture; when melted it formed a greenish-brown muddy liquid, and it was filtered before examination (*Cooking, Chem. and Drug.* 1908, 73, 74).

Berry wax from *M. cordifolia* came into prominence during the war. The plant is grown as a sand-binder in the neighbourhood of Cape Town, Port Elizabeth, and other places. The wax was previously exported to Germany, and

was used for gramophones and for floor polish (J. Soc. Chem. Ind. 1918, 37, 74 R).

Carnaúba or carnaúba wax is derived from the carnaúba palm, *Copernicia cerifera* (Mart.) (*Corypha cerifera*, Linn.), which grows in Brazil, especially in the provinces of Ceara, Rio Grande do Norte, and Piahy. The trunk is 25-35 ft. high with a crown of leaves at the top. The young leaves of about 3 ft. long have a coating of wax on both the upper and under sides, which appears homogeneous to the naked eye. The wax layer is thicker on the upper side, and comes off in scales; on the lower side it is thinner and more adherent. The harvesting extends over the six dry months of the year, and the leaves are cut twice a month, about eight leaves being cut from a palm at a time, those leaves that have reached a certain stage of development being taken, leaving the very young leaves to develop later. If the leaves are allowed to become too old the wax is easily detached, and is lost before the leaves are brought to the ground. The leaves are spread out to dry, and are then slit up with a knife and beaten over a cloth to detach the wax which comes off in scales or as a greyish-white powder. A little water is added to the powder, and it is melted and poured into moulds, in which it solidifies in cakes of about 2 kilos. About 850 leaves give 16 kilos. of wax; about 1.8 kilos. of wax, valued at 1s. 6d., are obtained from one palm. On poor land 1200 leaves, and on good land only 500 leaves are required to give the 16 kilos. In some estimates, however, the yields are not so good as these.

The following table, based on Hambloch's Reports on Brazil, Dept. Overseas Trade, 1919, 1921, and 1922, shows the exportation of carnaúba wax:

Year	Metric tons	Value in £	Value per metric ton in £
1913	3867	439,500	114
1914	3315	324,200	98
1915	5897	505,100	86
1916	4166	398,900	96
1917	3669	443,300	121
1918	4215	1,135,200	269
1919	6200		
1920	3500		
1921	1540	January to June (inclusive)	
1922	2200	" "	"

In 1913 Germany took 1710 metric tons; the United States 941; the United Kingdom 687; and France 509. In 1920 the United Kingdom took 1000 metric tons and the United States 2200.

Raw carnaúba wax is of a dirty yellowish or greenish colour, amorphous, hard, brittle, and easy to powder. In its outward appearance it is compact, but penetrated with very many air spaces; it is tasteless, and smells, when fresh, somewhat like fresh hay—i.e. of coumarin; later it becomes inodorous. It is purified by remelting, and has then a greenish-yellow or straw-yellow colour.

Analytical values.—The melting-point is variously given as from 80.5° to over 86°, it increases with the age of the sample, and an old specimen melted at 90°-91°; about 84° seems a common experience; light-coloured specimens have a somewhat lower melting-point than darker ones. The sp.gr. at 15° is 0.978-0.999.

The acid values recorded are from 0.3-10, about 4 being common; the saponification values from 60-85, and even 95; the iodine values from 5-14. In preparing bleached carnaúba wax additions, such as paraffin wax, are made so that the above values do not hold good for it. The wax is not easily saponified. Berg (Chem. Zeit. 1909, 33, 885) recommends the use of xylene as a solvent in order to hasten the saponification and to diminish the risk of oxidation occurring during long boiling with potassium hydroxide.

Composition.—Carnaúba wax is composed mainly of an ester of triacontyl, $C_{30}H_{61}$, with the acid $C_{27}H_{54}O_2$, which is either cerotic acid or an isomer of it. The triacontyl was formerly supposed to be the same as the melissyl of beeswax, but it now appears that melissyl is most probably $C_{31}H_{62}$. Carnaúba wax also contains a considerable proportion of free triacontyl alcohol $C_{30}H_{61}OH$. In addition there are a number of compounds present in small proportions.

Story Maskelyne (J. Chem. Soc. 1869, 22, 87) found: (a) melissin (melissyl alcohol) both free and coming from an ester; (b) a compound with m.p. 105°, corresponding to $C_{30}H_{61}O_2$; (c) an alcohol with m.p. 78°, corresponding to $C_{32}H_{66}O$, and also other compounds.

Von Pieverling (Annalen, 1870, 183, 344) prepared from this wax melissyl alcohol and examined its products, he also obtained a small quantity of ceryl alcohol $C_{27}H_{56}O$.

A long investigation of the composition was made by Sturcke (Annalen, 1884, 223, 283), employing carnaúba wax with m.p. 83°-83.5°. He found that the principal component was the ester $C_{30}H_{61} \cdot C_{27}H_{54}O_2$, and that there was a considerable quantity of free wax alcohol present. When the wax is extracted with boiling alcohol a considerable proportion dissolves but separates again when the alcohol cools. He found when 1200 grms. of wax were boiled out with 5½ litres of alcohol and the hot clear solution was poured off that on cooling 350 grms. (equivalent to 29 p.c.) were deposited. By repeated extraction small quantities of the ester seem to be removed each time; thus when 10 grms. of the wax were boiled with half-litre lots of alcohol, 350 c.c. of the ninth lot contained 0.295 grm. and of the tenth lot 0.286 grm. By saponifying the wax and separating the products with petroleum ether, &c., and by many fractionations he found: (1) A hydrocarbon with m.p. 59°-59.5° present in small proportion. (2) An alcohol $C_{26}H_{53} \cdot CH_2OH$ with m.p. 76° in small proportion. (3) An alcohol

with m.p. 85.5°-85.7° in large proportion. From this he prepared the acid $C_{28}H_{56} \cdot COOH$ with m.p. 80°-80.2°. This alcohol he called myricyl (melissyl) alcohol, but according to Heiduschke and Gareis (J. pr. Chem. 1919, 99, 299) it contains CH_2 , less than the melissyl alcohol $C_{31}H_{64}O$ obtained from beeswax. (4) A dihydroxy alcohol $C_{29}H_{58}(OH)_2$ with m.p. 103.5°-103.8° in small proportion. From this he prepared the acid $C_{28}H_{56}(COOH)_2$ with m.p. 102.5°. (5) An acid $C_{28}H_{56} \cdot COOH$ with m.p. 72.5° in small proportion, isomeric with lignoceric acid. This acid was subsequently

called carnaubic acid by Darmstaedter and Edischkita (Ber. 1896, 29, 620) in a paper on wool fat. (8) An acid $C_{15}H_{31}COOH$ with m.p. 78°-79°, either identical or isomeric with the cerotic acid of beeswax, in large proportion. It would not crystallise when it solidified from the melted state, and for this reason he doubted its identity with the cerotic acid of beeswax.

(7) A lactone $C_{15}H_{31}<\begin{smallmatrix} CH \\ CO \end{smallmatrix}>O$ with m.p. 103°-5° in small proportion. From this he prepared the acid $C_{15}H_{31}(COOH)$, with m.p. 89°-5°-90°.

It should be noted that these products were obtained after saponification. The hydrocarbon, no doubt, was free in the wax, and the $C_{15}H_{31}CH_2OH$ alcohol probably was partly free and partly came from the ester, but the others were not proved to be free before saponification. Besides these Stürcke also noticed, as had von Pieverling, a greenish balsam-like substance with an odour like coumarin, but in too small quantity for examination. Stürcke's results, it should be remarked, do not fully explain the analytical values given above, so further work on the composition is needed.

Liebermann (Ber. 1885, 18, 1979) obtained a substance from the wax by a great many fractional crystallisations with m.p. 92°, which could not be materially raised by further crystallisations; it formed a matted paper-like layer without any lustre; he did not, however, make an analysis of it.

Heiduschka and Gareis's work (J. pr. Chem. 1919, 99, 293) is described above under the composition of beeswax.

Bibliography.—Brande (Phil. Trans. 1811, 261), action of various solvents and reagents. Lewy (Ann. Chim. 1845, [3] 13, 449), percentage of carbon and hydrogen. Bérard (Bull. Soc. chim. 1868, 9, 41) found cerotic acid (a mistake probably) and an ester saponifiable by fusion with potassium hydroxide. Story Maskelyne (J. Chem. Soc. 1869, 22, 87), see above. Von Pieverling (Annalen, 1876, 183, 344), see above. Stürcke (*ibid.* 1884, 223, 283), see above. Valenta (Zeitsch. anal. Chem. 1884, 23, 257), melting-point of mixtures of this wax with commercial stearic acid, with mineral wax and with paraffin. Liebermann (Ber. 1885, 18, 1979), see above. A. and P. Buisine (Bull. Soc. chim. 1891, [3] 5, 654), effect of this wax as an adulterant of bees wax. Schaedler, Technologie der Fette und Öle, 2nd ed. 1892, 881. Gascard (J. Pharm. Chim. 1893, [5] 28, 49) prepared wax alcohols from beeswax, carnauba wax, and lac, and believed them to be melissyl alcohol in each case. The melting-point of those from carnauba wax and lac was 88°, and he purified that from beeswax and got its melting-point up to 88° by making its ester with melissic acid and then decomposing this. Villon (Bull. Soc. chim. 1893, [3] 9, 1046), collecting, bleaching, and uses. Brant, Fats and Oils, 2nd ed. 1896, ii. 144. Semler, Tropische Agrikultur, 2nd ed. 1897, i. 732. Lewkowitzsch (Analyst, 1899, 24, 319), acetyl values. Kichhorn (Zeitsch. anal. Chem. 1900, 39, 640), directions for finding the acid and saponification values, using amyl alcohol as solvent, thus facilitating saponification. Berg (Chem. Zeit. 1903, 27, 754), detection and analytical results. Radcliffe (J. Soc. Chem. Ind. 1906, 25, 188), analytical values, using amyl

alcohol as solvent. Engler (Chem. Zeit. 1906, 30, 711), the rotatory power. Berg (Chem. Zeit. 1909, 33, 885), xylene as solvent for finding analytical values. Leys (J. Pharm. Chim. 1912, [7] 5, 577), describes a new method of examining this wax and beeswax; he uses a mixture of amyl alcohol and fuming hydrochloric acid to dissolve the wax alcohols and separate them from the hydrocarbons; he found no hydrocarbons in carnauba wax. Lüdecke (Seifensieder Zeit. 1913, 40, 1237, 1274, 1302, 1327), descriptions of the commercial varieties, adulterants (fragments of candellilla wax are sometimes mixed in), detailed methods of finding melting-point, sp.gr., and analytical values. Buchner (Chem. Zeit. 1918, 42, 373) quotes Popp on the formula of melissic acid prepared from carnauba wax (Heiduschka and Gareis do not agree with Popp's formula). Heiduschka and Gareis (J. pr. Chem. 1919, 99, 293) compare melissyl alcohol from beeswax and its derivatives with the alcohol from carnauba wax and its derivatives and find them to differ by CH_2 .

Cochin China wax (*Cay Cay fat*, *Irvingia butter*). This is obtained from the fruit of the Cay Cay tree, *Irvingia Oliveri* (Pierre), a forest tree reaching the height of 100 ft., and growing widely in the east of Cochin China. The fruit is the size of a lemon, the endocarp has the size and shape of an almond with its outer covering, and the kernel, too, resembles in size and shape that of the almond. The fruits are ripe in July, and fall to the ground; they are gathered into heaps by the natives, and left for two months to allow the soft outer parts to decompose; they are then carried to the houses and dried in the sun. They are opened with a strong knife, and the kernels are removed, dried in the sun, and pounded in a mortar. The pulp is placed in a vessel having a bottom of plaited material; this is fixed above water in another vessel, and the water is heated, but not to boiling. When the pulp has become a sticky paste it is wrapped in a mat of rice straw, and submitted to pressure in a crude press, the operations being repeated several times, and the melted wax is either allowed to solidify in moulds or else is cast into candles in bamboo tubes. In the laboratory the dry kernels extracted with carbon disulphide gave 52 p.c. of wax. The wax is of a greyish-yellow colour, and is unctuous to the touch. The purified wax softens at 37°, melts at 38°, and solidifies at 34° (Vignoli, Le Cay Cay, Thèse présentée à l'Ecole Supérieure de Pharmacie de Montpellier, 1886).

Bontoux (Les Matières Grasses, 1908, 1276; J. Soc. Chem. Ind. 1909, 28, 429) found that 100 dry seeds weighed 360 grms. and gave 73 p.c. of shells and 22 p.c. of kernels. The latter, on extraction with light petroleum, gave 60.45 p.c. of wax. The wax had the consistency and texture of beeswax, and was more brittle, with the same conchoidal fracture; its sp.gr. at 40° compared with water at 40° was 0.913; it melted at 39.7° in a capillary tube, and solidified at 31°; its acid value was 0.86; saponification value 235.3; unsaponifiable matter 0.42 p.c.; iodine value 6.7; Reichert-Meissl value 0.62. The insoluble fatty acids, together with the unsaponifiable matter were 94.0 p.c., their m.p. was 38.8°; solidifying point (titer test) 36.6°; neutralisation value 250.2;

and mean molecular weight 224. Two samples of the wax of native origin had nearly the same values, but the acid values were 23.5 and 34.0, which, however, are not excessive, and they contained 0.16 p.c. and 0.19 p.c. of unsaponifiable matter. Bontoux prepared methyl esters, and concluded that the wax was mainly composed of myristin 60-65 p.c., laurin 30-35 p.c., and about 5 p.c. of olein. The wax gives a hard white soap. The production in Indo-China has declined, owing to the introduction of petroleum. A Cay Cay wax is also obtained from the fruit of the tree *Irvingia malayana* (Oliver), which grows in Cambodia. Other references are: Heekel, *Annales de l'Institut colonial de Marseille*, 1893; Apoth. Zeit. 1898, 169; Crevost, *Les arbres à suif de l'Indochine*, Hanoi, 1902; Bulletin économique de l'Indochine, Hanoi, 1902; Chem. Zeit. 1903, 27, 43.

Cow tree wax (Milk tree wax). In the north of Venezuela, in the neighbourhood of Caracas and of Lake Maracaibo, and in the valley of Caneagua, there grows a tree (*Brosimum Galactodendron*) called *Palo de vaca* or *Arbol de leche*, which yields a thick milk when incisions are made in its trunk; this is drunk like milk by the inhabitants. This milk, when heated, forms a skin, and if this is removed and evaporation continued, an oily liquid is obtained, together with a fibrous mass. The oily liquid when it has solidified, is a yellowish-white, hard translucent wax; it begins to melt at 40°, and is completely melted at 60°. It is insoluble in water, but is easily dissolved by essential oils. It dissolves in boiling alcohol and separates on cooling; it is saponifiable by caustic potash. It can be used like beeswax for making candles. Humboldt, *Ann. Chim.* 1817, 7, 182; Boussingault and Mariano de Rivero, *ibid.* 1823, 23, 219; Marchand, *J. pr. Chem.* 1840, [i.] 21, 43.

Esparto grass wax. In preparing the fibre of this grass for paper making the material reaches the mills in tightly compressed bales. It is there loosened by a special machine and at the same time freed from dust by a strong current of air from a powerful fan. This dust contains from 25-50 p.c. of wax, and in most mills is deposited in special dust collectors. The wax when obtained from the dust is hard, rather brittle, and of a light brown colour, and has the following characteristics: m.p. about 74°, loss of weight at 100° overnight about 1.5 p.c., ash 0.02 p.c., acid value 34.42, saponification value 71.41, iodine value 6.48, unsaponifiable matter (soluble in hot CCl_4) 50.34 p.c., fatty acids 45.69 p.c. The wax is in demand by some manufacturers and commands a good price; but unfortunately the quantity of dust obtainable at any one paper mill is not very large, so the output of wax is not equal to the demand (Budds, *J. Soc. Chem. Ind.* 1916, 35, 401).

Fig tree wax (Gondang or Kondang or Getah wau, Jass or Sumatra wax). This wax is obtained in Java from the milky juice (*getah* in Malay) which runs from incisions made in the bark of the gondang, a wild fig tree (*Ficus variegata*, Blume. = *F. cerifua*, Jungh. = *F. suberosa*, Blume.). The juice is boiled with water until the wax separates. It forms a fairly hard cake, cream coloured within, turning brown in the air; it has a conchoidal fracture and can be powdered, but not readily. The

grade wax melts at about 80° to a very viscous mass, which, on cooling, remains viscous for a long time, and from which an aqueous liquid separates. The sp.gr. of the wax after melting is 1.015 at 15°. It softens at 55°, and is only completely melted at 73°. It is soluble in benzene, chloroform, carbon disulphide, oil of turpentine, light petroleum, and boiling ether. Boiling alcohol dissolves it slowly, and the greater part separates on cooling. Cold alcohol keeps in solution a little over 5 p.c. of the wax. By means of boiling alcohol over 70 p.c. of white crystalline purified wax can be obtained, melting at 61°, insoluble in cold alcohol, but soluble in boiling alcohol. Greshoff and Sack (*Rec. trav. chim.* 1901, 20, 68), by analyses and saponification of the wax thus purified, obtained results suggesting that it is an ester $\text{C}_{20}\text{H}_{40}\text{O}_2$ of an alcohol $\text{C}_{17}\text{H}_{34}\text{O}$ (floceryl alcohol), with m.p. 198°, and of an acid $\text{C}_{12}\text{H}_{24}\text{O}_2$ (floceric acid), with a m.p. 57°, this ester is probably associated with some accessory substance; they also think the original wax contains some free floceryl alcohol.

Vogl (Lotos, published at Prag, 1872, 22, 54) describes Sumatra wax or Getah Lahoe coming from the same tree. Kessel (*Ber.* 1878, 11, 2112) assigns formulae to components of the wax which differ from the above. Ultee (*Chem. Zeit.* 1915, ii, 794, from *Pharm. Weekblad* 1915, 52, 1097) examined the milky sap of *Ficus variegata*; it contained 35 p.c. of solids, and when coagulated by heating, or by alcohol, or by dilute acetic acid it yielded gondang wax. From this by suitable treatment, including a saponification, he obtained a wax alcohol, the floceryl alcohol of Greshoff and Sack. This alcohol he identified as being the same as β -amyrin with m.p. 197.5°. (β -amyrin is $\text{C}_{20}\text{H}_{40}\text{O}$ and comes from elemi resin.) In the wax itself he found lupeol acetate with m.p. 190°-197°, but no free β -amyrin.

Insect wax. This is also called *Chinese wax*, *Chinese tree wax*, *Vegetable spermaceti*, and sometimes, but incorrectly, *Japanese wax*; it must not be confused with Japan wax. It is the secretion of an insect *Coccus pela* (Westwood), *Coccus ceriferus* (Fabr.). The industry of its production is peculiar, in that the insects are bred for the purpose of producing eggs in one district, and these eggs are then transported to another district where the insects are reared to produce wax. The Chien-Chang valley in the prefecture of Nung Yuan Fu (Long. 102° 28', Lat. 27° 54') in the Sze Chuan province of China is the great breeding-ground of the wax insect; it is about 5000 ft. above sea-level. Here the insects are reared on the *Ligustrum lucidum* (Ait.) or large-leaved privet. In March, when the trees were seen by Mr. Hosie, he found numerous brown pea-shaped excrescences attached to the bark of the boughs and twigs. The larger of these were readily detachable, and when opened presented either a whitish-brown pulpy mass or a crowd of minute animals like flour, whose movements were just perceptible to the naked eye. From 2 to 3 months later these had developed in each case into a swarm of brown creatures, each provided with six legs and a pair of antennae; each of these was a wax insect. Two hundred miles to the north-east of the Chien-Chang valley, and separated from it

by a series of mountain ranges, is the prefecture of Kia-ting-fu (Long. 104° , Lat. $29^{\circ} 34'$), also called Chia-ting-fu, containing the district of Omi and the valley of the Ya river, the headquarters of the wax-producing industry. The scales produced in the Chien-Chang valley are ready for removal by the end of April, and are then full of eggs; they are made up into paper packets, each weighing about 16 oz. Sixty of these packets make a load, and are conveyed by coolies from the Chien-Chang valley to the town of Hung Ya in the Kia-ting-fu prefecture for sale to the farmers. In May thousands of coolies are engaged in the traffic. They travel only at night, in order to avoid the high temperature of the day, which would tend to the rapid development of the insects and their escape from the scales. At the stopping places the packets are opened out in cool places; but in spite of this, each packet is found to have lost on an average an ounce in transit. A pound of scales laid down in Kia-ting-fu, in years of plenty, costs about half a crown; in bad years the price is doubled. In favourable years a pound of scales will produce 4-5 lbs. of wax. In the plain around Kia-ting-fu the plots of ground are thickly edged with stumps of *Fraxinus chinensis* (Roxb.), a species of ash varying from 3 or 4 to 12 ft. high, with numerous sprouts rising from their gnarled heads, and resembling at a distance pollard willows. On the arrival of the scales they are made up into small packets enclosed in a leaf of the wood-oil tree. The edges of the leaf are tied together with a rice straw, by which the packet is suspended close under the branches of this ash. A few rough holes are drilled in the leaf with a blunt needle, so that the insects may find their way through to the branches. On emerging from the scales the insects creep rapidly up to the leaves, among which they remain for a period of 13 days. They then descend to the branches, on the underside of which they take up their position, and commence to deposit the wax. This first appears as an under-coating on the sides of the boughs and twigs, and resembles quinine sulphate or a covering of snow. It gradually spreads over the whole branch, and attains, after 3 months, a thickness of about a quarter of an inch. After the lapse of 100 days the deposit is complete, the branches are lopped off, and as much of the wax as possible is removed by hand. This is placed in an iron pot of boiling water, and the wax on rising to the surface is skimmed off and placed in a round mould, whence it emerges as the insect wax of commerce. Where it is found impossible to remove the wax by hand, the twigs and branches are thrown into the pot, so that this wax is darker and inferior. The insects which have sunk to the bottom of the pot are placed in a bag and squeezed of the last drop of wax, and are then thrown to the pigs. Not only the *Fraxinus chinensis*, but also the *Liquidum lucidum* is used in the final wax-producing stage of the industry. The wax is used for coating the exterior of animal and vegetable tallow candles, as it serves to hold in the more fusible tallow when the candle is burning; a little is also mixed with the tallow; it is employed to give a gloss to paper, for coating wood and for a polish for furniture and iron-ware

(Nature, 1891, 43, 291; Wilson, Chemist and Druggist, 1906, 68, 143; Bull. Imp. Instit. 1924, 22, 64; Pharm. J. 1924, 27, 278).

Insect wax is white and crystalline, resembling spermaceti in appearance, but it is harder and more fibrous; it is brittle, and at 15° can be powdered. Its sp.gr. is 0.970 at 15° (0.926 at 15° , Gehe and Co., Zetsch. anal. Chem. 1895, 34, 765) and 0.809-0.811 at 98° - 99° ; m.p. 80° - 83° ; saponification value 80-83; iodine value 1.4. It is only very slightly soluble in alcohol and ether, but is readily soluble in naphtha, from which it can be crystallised. Brodie (Phil. Trans. 1848, 159) saponified the wax by melting it with potash, and obtained an alcohol and an acid; the alcohol he named *cerotin*, and to it he assigned the formula $C_{17}H_{34}O$, it is now called *ceryl alcohol*; the acid he considered to be the same as the cerotic acid he had obtained from beeswax, to which he had assigned the formula $C_{27}H_{54}O_2$; the wax he regarded as ceryl cerotate, the ester of this alcohol and acid. Brodie's formulæ have been supported by Gascard (*see below*). Marie (J. Chem. Soc. 1897, 72, i. 318) proposes $C_{26}H_{52}O_2$ or $C_{25}H_{50}O_2$ for the cerotic acid of beeswax; and Henriques (*ibid.* 460) regards ceryl alcohol and cerotic acid from insect wax as $C_{26}H_{52}O$ and $C_{26}H_{52}O_2$, and it is stated that the identity of the cerotic acids from insect wax and from beeswax is not quite certain. Other substances besides ceryl cerotate are probably present.

Gascard (Compt. rend. 1920, 170, 1326) investigated the formulæ for the ceryl alcohol and for the cerotic acid obtained from insect wax, and confirmed those of Brodie, namely, $C_{17}H_{34}O$ with m.p. 80° for the alcohol and $C_{27}H_{54}O_2$ with m.p. 82° - 82.5° for the acid; but thought that the acid must be different from the cerotic acid of beeswax that Marie prepared with m.p. 77.5° . The following was his method. He started with insect wax with m.p. 80.5° - 81° , and first purified the ester, ceryl cerotate, by extraction with boiling acetone; the undissolved ester after recrystallisations from benzene melted at 84° . He saponified by boiling with alcoholic potassium hydroxide. He then added calcium chloride and obtained a precipitate of calcium cerotate; from the filtrate he obtained the ceryl alcohol which, after purification, melted at 79° - 80° . From this he prepared the iodide and found that the percentage of iodine in it corresponded to $C_{17}H_{33}I$. From the iodide he obtained the hydrocarbon which melted at 59.5° ; thus agreeing with Kraft's $C_{17}H_{34}$. As regards the acid, he obtained it from the calcium cerotate and found that it melted at 82° - 82.5° . He also prepared some from the ceryl alcohol by oxidation with potassium bichromate in acetic acid solution; after purification it melted at 81.5° - 82° , and by titration he found that its molecular weight corresponded to $C_{27}H_{54}O_2$. By further purification it melted at 82° - 82.5° , like the acid got by saponification.

Japan wax (Japan tallow, *Sesamum* seed, Vegetable wax of Japan). This must not be confused with insect wax which has sometimes been called Japanese wax. Japan wax is one of the most important of the vegetable waxes, large quantities being exported from Japan. Before 1854, whilst Japan was closed to foreign

merchants except to the Dutch, it came through China and Singapore, and was imported in small quantities coming in small thin cakes, but after the opening of certain Japanese ports to British merchants, it arrived in large quantities and in square blocks or cases of about a picul each (133½ lbs.).

It is derived from the berries of three species of *Rhus* that grow in Japan, namely, *R. succedanea*, L., *R. vernicifera*, De C., and *R. sylvestris*, S. and Z. *R. succedanea* grows in the southern parts of Japan and yields wax only, but *R. vernicifera*, which has a more northerly range, yields a more important product, namely, the well-known Japanese lacquer, which is prepared from its sap, but its berries are also used as a source of wax. *R. sylvestris* is a less important source. *R. succedanea* and *R. vernicifera* also grow in China. The berries of all three are composed of an outer skin, a mesocarp in which is the wax, and a kernel.

In Japan to obtain the wax the berries are reduced to a meal—some authors say that they are previously slightly roasted; the meal is heated by steam in hempen sacks and then quickly squeezed in a wedge press to force out the wax. The residue is again treated in the same way. In the case of *R. vernicifera* the kernel is easily separated and is removed in the course of crushing, but in the case of *R. succedanea* the wax adheres to the kernel in spots, and it is not clear from the accounts of the process whether the kernel is separated or crushed with the mesocarp. The methods, no doubt, vary in different localities. It has been stated that perilla oil is added to obtain the last portions of the wax, but this is denied by Tsujimoto (Lewkowitch and Warburton, Oils, Fats, and Waxes, 6th ed. vol. ii. 1922, p. 45), who states that a proportion of the kernel oil of *R. succedanea* is added. With respect to this oil, A. Meyer (Arch. Pharm. 1879, [3] 15, 119, 120) found in the cotyledons contained in the kernels of *R. succedanea*, after carefully removing the shells, 36 p.c. (30 p.c. ?) of fat, or 2.65 p.c. on the whole fruit. It was yellowish-green, melted at 30°, was not a drying oil, and dissolved in about 30 parts of alcohol at 30°. Crowe (Consular Rep. for Japan for 1912, p. 43) says that by the use of benzine an additional 10 p.c. of wax can be obtained, and that several works were adopting the system.

The yield is from 15 to 25 p.c. Impurities are removed by melting and skimming off the clear wax. It is bleached by melting it and allowing it to drop through woollen bags into cold water, so as to subdivide it into small pieces. These are exposed to the sun and are sprinkled with water and frequently turned over; the process occupies about 30 days.

The wax is pale yellow and hard with an even or conchoidal fracture; it becomes yellow brown on keeping, and acquires a white powdery surface. The m.p. varies from 48° to 55°, that usually found being 53°; the wax solidifies again at about 41°, and when recently solidified melts at 42°; it slowly regains the higher melting-point. It is said that on warming it becomes transparent 10°–12° below its melting-point (Schaeffler).

Its specific gravity is close to that of water, and as it contracts and expands at a greater

rate than water, it exhibits the peculiar property of sinking, hovering or floating in water at different temperatures, sinking in cold water and floating in water somewhat warmer. After melting and resolidifying its specific gravity is lowered, it rises again in the course of some months. Thus a sample which hovered at 16.2° was melted and resolidified, it then hovered at 8.0°. Remembering that its expansion is greater than that of water, its specific gravity at 16.2° would be materially less than it was before melting, and it would float in water of that temperature. There is some variation in the specific gravity of different samples.

It is readily soluble in benzene and petroleum-ether and sparingly soluble in cold ether; it is insoluble in cold alcohol, but dissolves on warming and separates again on cooling.

In and after 1900 the following analytical values have been recorded: Acid value, 11.2–32.6; it is very variable, but values between 14 and 20 seem most common. Saponification value, 206.6–237.5; values between 215 and 224 being common. Iodine value, 8.3–15.1. Hubl, in 1884, records the iodine value as 4.2, so it is thought that the method of obtaining the wax has been changed. Part of the iodine value has been ascribed to the use of perilla oil mentioned above, as this oil has a very high iodine value. Ahrens and Hett in some wax prepared from berries obtained from Japan found iodine values of 11.9–12.8, and after bleaching in the sun, of 7.6.

Composition.—Japan wax is chiefly composed of glyceryl palmitate together with some free palmitic acid. Besides these a good many other substances have been obtained from it in small proportions; they may have been free in the wax or may have come from esters. These substances are: (1) About 1 p.c. of janic acid $C_{11}H_{21}O_4$ with m.p. 117°–117.0°; it is normal nonadecamethylene dicarboxylic acid $CO_2H \cdot (CH_2)_{11} \cdot CO_2H$. There is some evidence that the janic acid comes from a mixed ester of glycerol with janic acid and palmitic acid existing in the wax. (2) and (3) Smaller proportions of the two next lower acids, namely,

(4) Five to six per cent. of acids soluble in water, perhaps including suberic acid and isobutyric acid. (5) An odour of cœnanthyl aldehyde is given off during saponification. This may be due to the oxidising action of bleaching agents, products being formed from which potassium hydroxide liberates cœnanthyl aldehyde. (6) Pelargonic acid. (7) An acid with m.p. 87° and formula $C_{11}H_{21}O_2$ or $C_{10}H_{19}O_2$. (8) and (9) Very small quantities of liquid acids, one insoluble in water and one soluble. (10) and (11) Very small quantities of oleic and stearic acids, perhaps due to some addition made in the course of the manufacture of the wax.

The unsaponifiable matter resembles cœnant in appearance, and is recorded as from 0.54 p.c. to 1.63 p.c.; in it have been found: (12) Melissyl alcohol with m.p. 88°. (13) Ceryl alcohol with m.p. 79°. (14) A saturated alcohol with m.p. 65° and with formula $C_{11}H_{23}O$. (15) A phytosterol with a double binding and m.p. 130°. As air-dried it is $C_{11}H_{21}O.H_2O$, its specific

rotatory power is -22.11° , nearly the same as that of the phytosterol of cotton-seed oil. (16) About 60 p.c. of the unsaponifiable matter is a mixture of liquids, unsaturated and containing oxygen.

Uses.—It is only the bleached wax that is exported. It is said to be used for floor, furniture, and boot polishes and in laundry work; but there appears to be some secrecy about its exact use. Added to beeswax it imparts more solidity to the candles and causes them to leave the mould more easily; it is used instead of beeswax for a similar purpose in some rubber factories. Before 1859 the wax or the free acids obtained from it was used for candles and night-lights (Wilson, J. Soc. Arts. 1858-59, 7, 424). Lewkowitsch and Warburton (Chem. Tech. of Oils, Fats and Waxes, 6th ed. vol. ii. 1922, p. 667), however, says that the difficulties of employing Japan wax fatty acids for candles have not yet been overcome. It emulsifies well with water and has been used for currying leather (J. Soc. Chem. Ind. 1898, 17, 167). In Japan it is used for polishing turned wood and cabinet work; unbleached it is used for the candles of the jinriksha men and (unbleached?) in a composition for keeping the women's hair glossy and straight.

Bibliography.—Japan wax, like other substances which are of pharmaceutical interest, has a long bibliography. Kaempfer (Amoenitates Exoticae, 1712, pp. 791, 794); Thunberg (Flora Japonica, 1784, p. 121); Siebold (Voyage au Japon, 1823-30, published 1838, i. p. 276). These three authors were surgeons in Dutch employ, and thus were enabled to visit Japan when it was closed to other Europeans; they mention the wax and the trees from which it was obtained. Oppermann (Ann. Chim. 1832, 49, 240), percentage composition. Landerer, H. Müller and Buchner (Repert. f. d. Pharm. 1833, 44, 1-34), discussion and experiments as to whether Japan wax is identical with adipocere from dead animals, and whether it is a North American product. Nees von Esenbeck (*ibid.* 1833, 46, 283), commenting on Landerer's work, says that he has seen wax from *R. succedanea* from Japan, and that it is quite the same as that found in commerce. Trommsdorff (J. pr. Chem. 1834, 1, 151), properties and trial as a candle. Brandes (Arch. Pharm. 1841, [2] 27, 288), composition. He thought that Japan wax was composed of the supposed compound ceric acid that Hess (Pogg. Ann. Phys. Chem. 1838, 43, 382) obtained by the treatment of rye-starch with nitric acid. Sthamer and Meyer (Annalen, 1842, 43, 335), composition, distillation, and oxidation by nitric acid. They found that Japan wax is glyceryl palmitate. Hanbury (Pharm. J. 1852-53, [1] 12, 476, and Hanbury's Science Papers, 1876, 60), description and melting-point. Berthelot (Ann. Chim. 1854, [3] 41, 242) suggested that Japan wax perhaps contains a dipalmitin. Simmonds (J. Soc. Arts, 1858-59, 7, 611) and Wilson (*ibid.* p. 424), source and use for candles and night-lights. The Pharm. J. (1859-60, [2] 1, 176), the J. Pharm. Chim. (1859, [3] 56, 368), and the Neues Repert. f. Pharm. (1860, 9, 74) give summaries from various authors. Jackson and Rogers (Proc. Boston Soc. Nat. Hist. 1859-61, 7, 54, 58), properties. Kopp (Rep. Chim. Appliquée, 1860,

2, 142 and 296), discussion of Jackson and Rogers' work; the melting-points were incorrectly reported on p. 142. Bleekrode (*ibid.* p. 368), particulars some incorrect, also questioning the identity of the wax examined by previous authors. Simon (Bull. Soc. Imp. Zoo. D'Acclimation, 1862, 9, 596). He was an agent of the Ministre de l'Agriculture and wrote from Nagasaki, giving particulars of the exploitation per 10,000 trees of *R. succedanea* occupying 2 hectares and of the preparation of the wax. Roucher (J. Pharm. Chim. 1872, [4] 16, 20), peculiarities of the melting-point and use in pharmacy for making cerates with olive oil. Ludwig (Arch. Pharm. 1872, [3] 1, 213), particulars. Robertson (Consular Report on Trade of Kanagawa in Japan, 1874, 64; also in J. Soc. Arts, 1873-74, 22, 787; also in Pharm. J. 1874-75, [3] 5, 584), source and preparation. Further particulars about source, preparation and use (J. Soc. Arts, 1873-74, 22, 1000; also in Pharm. J. 1874-75, [3] 5, 425). *Naturalizing R. succedanea* in France (Pharm. J. *ibid.* p. 448). Gribble (Arch. Pharm. 1876, [3] 8, 374, from Handels-Bericht of Gehe and Co., Dresden, 1875), preparation written in Nagasaki. Cooke (Oilseeds and Oils in the India Museum, 1876, p. 5), particulars. Summonds (J. Applied Science, 1877, 8, 55), particulars. Buri (Arch. Pharm. 1879, [3] 14, 403), composition. He saponified and examined the mixed acids and found palmitic acid chiefly, but that others were present, including at least one with melting-point above that of stearic acid, and also an oleic-like acid in small proportion. A. Meyer (Arch. Pharm. 1879, [3] 15, 97), a long paper discussing the work of previous authors and describing the *Rhus* trees with figures of leaves, flowers and fruit of *R. succedanea*, and giving results of a few experiments. Hübl (Dingl. poly. J. 1884, 253, 289), iodine value. Eberhardt (Inaug. Diss. Strassburg, 1888), composition. He found the acid afterwards named janicic acid by Geitel and van der Want. Rein (Japan: Travels and Researches, 2nd ed. 1888). Rein (The Industries of Japan, 1889, 158-164), an account of the three *Rhus* trees and of the preparation of the wax. Kleinstück (Chem. Zeit. 1st. 0, 14, 1303), peculiarities in the specific gravity. Watt (Dict. Econ. Prods. of India, vol. vi pt. 1. 1892, 499, 500, and Commercial Prods. of India, 1908, 914). Schaedler (Technol. Fette und Öle, 2nd ed. 1892, 80, 870), particulars of the wax and also of its m.p. peculiarities. Hehner and Mitchell (J. Amer. Chem. Soc. 1897, 19, 49, and Analyst, 1896, 21, 330), abnormal behaviour of palmitic acid from Japan wax when mixed with stearic acid. La Wall (Amer. J. Pharm. 1897, 69, 18), starch as an adulterant. Lewkowitsch (Analyst, 1899, 24, 319), analytical values and effect of acetylling. Bull. Bot. Dept. Jamaica, 1900 [2] 7, 37, source and preparation of the wax. Geitel and van der Want (J. pr. Chem. 1900, [2] 61, 151), composition. Eichhorn (Zeitsch. anal. Chem. 1900, 39, 640), directions for finding acid value and saponification value, using amyl alcohol.

In this Century.—Bernheimer and Schiff (Chem. Zeit. 1901, 25, 1008), analytical values. Ahrens and Hett (Zeitsch. angew. Chem. 1901, 684), change in analytical values between wax of recent and of former years. Berg (Chem.

Zeit. 1903, 27, 755), analytical values. Lemarié (Imp. Inst. Bull. 1903, 1, 209), methods of manufacture and uses. Schaal (Ber. 1907, 40, 4784), composition, the acids examined by distillation in vacuum. Benedikt-Ulzer (Anal. Fette und Wachstern, 5th ed. 1908, p. 883), particulars. Matthes and Heintz (Arch. Pharm. 1909, 247, 650), composition of the unsaponifiable matter. Tassily (Bull. Soc. chim. 1911, [4] 9, 608), composition by Haller's alcoholysis method (Compt. rend. 1906, 143, 657), namely, by conversion into methyl esters. Crowe (Consular Rep. for Japan for 1912, p. 42), export and uses. Lewkowitch and Warburton (Chem. Technol. and Anal. of Oils, Fats and Waxes, 6th ed. vol. ii. 1922, 45, 661), particulars, analytical values and uses. (See also this Dictionary, vol. iii. 692).

Mexican myrica wax (*Mexican myrtle wax*). This wax is obtained by the Indians in Mexico from the fruit of *Myrica jalapensis*, and is sold in Mexico city, where it is used for making candles. The tree is known locally as 'arbol de la cera,' and occurs in Vera Cruz, sometimes in dense thickets covering considerable areas. The wax forms a greenish-white layer on the outer surface of the fruit, and is obtained by boiling the fruit in water and skimming off the floating melted wax; it is refined by melting and straining. On examination it gave the following values, which resemble those of Cape berry wax: sp.gr. 0.8763 at 99°; m.p. 43.2°; acid value 4.07; saponification value 214.5; iodine value 238. It is considered that it would be suitable for making candles and soap (Olsson-Seffer, Bull. Imp. Inst. 1909, 7, 410).

Myrtle berry wax (*Myrtle wax, Laurel wax, Bayberry tallow*) is obtained from the wax myrtle, *Myrica cerifera* (Linn.), a shrub growing on peaty soil in North America, and common along the North Atlantic sea coast. The fruit is brown or blackish and the size of a pea; it secretes the wax and becomes covered with a snow-white crust, penetrated by brown or black points of the skin, so that the wax can only be got off as a powder and not in coherent pieces.

Wax is also got from other Myricaceae, namely, *M. caracasana* (Humb. and Bonpl.) in South America, especially in Colombia and Venezuela, and *M. aethiopica* (Linn.) in Abyssinia. See also *Cape berry wax* and *Mexican myrica wax* above.

To obtain the wax the berries are boiled with water, and the fatty mass that floats on the surface is skimmed off and poured into flat dishes; the yield of wax is from 20 to 25 p.c., and a bush yields from 10 to 15 kilos. of berries. The wax which comes from the United States has a deep green colour, probably due to chlorophyll; this colour is bleached to a grey-yellowish tint by exposure to light and air for several years, but the change extends only a few millimetres below the surface.

The statements as to its composition are not concordant. Smith and Wade (J. Amer. Chem. Soc. 1923, 25, 629), however, examined the wax, preparing it by extracting the berries with light petroleum, and concluded that it was mainly palmitin (glyceryl tripalmitate) with some lower glyceride and a small amount of

free acid; they obtained pure palmitin by crystallising four times from light petroleum. The berries they used were picked in September, and the extraction and examination were made in November. The values they record are: sp.gr. 0.9806 at 22°/15.5°, and 0.879 at 99°/15.5°; refractive index at 80° 1.4363; acid value 30.7; saponification value 317; iodine value (Hübl) 3.9; Reichert-Meissl number 0.5. From these they inferred the absence of oleic and volatile acids. They also concluded that no stearin was present. The m.p. in this sample was 48°, as determined by Allen's method (Coml. Organ. Anal. 3rd. ed. vol. ii. pt. i. 34), and the solidifying point was 45°; but it was found that the melting-point rises considerably on keeping the wax. A redetermination in March of the m.p. gave it as 52.5°, a rise of 4.5° in 4 months. A specimen of wax about 4 years old melted at 57° and solidified at 58.3°. Wax from berries obtained in August and extracted in March melted at 55.4°.

Some other observers have found the acid value to be only about 4. It is inferior to beeswax in ductility and plasticity; mixed with beeswax it can be employed for making candles; these are said to give a pleasant smell when extinguished. It could probably be used for soap making. Chittenden and Smith (Amer. Chem. J. 1884, 6, 217) employed this wax as a source for preparing pure palmitic acid.

Some wax prepared in Colombia from the berries of *M. arguta* was examined at the Imperial Institute (Bull. Imp. Inst. 1918, 16, 287) with the following results: m.p. 45°; solidifying point of the fatty acids 46.4°; acid value 21.2; saponification value 216.7; iodine value 1.03; unsaponifiable matter 0.4 p.c.; the wax was yellowish-buff in colour and had a peculiar odour, similar to that of myrtle wax from South Africa (Cape berry wax). It was stated that the wax is employed in Colombia for the manufacture of soap and candles, that the plant is abundant, that the fruit can be gathered cheaply and easily, and that the extraction of the wax is not difficult.

Ocuba wax is obtained from the fruit of a shrub growing in the Pará province of Brazil. It grows well in marshy places, and is found in abundance along the banks of the Amazon river. The fruit encloses a nut covered with a thick skin. The skin extracted by water gives a fine red colour (Ocuba red); after washing with water the nuts are thrown in heaps, crushed to a paste, and boiled, when the wax separates and floats on the surface. The crude wax resembles beeswax, and by purification can be obtained white and suitable for candle-making. 100 kilos. of the seeds give 20-22 kilos of wax. The product is said to be a mixture of wax, fat, and resin, to melt at 40°, and to have a sp.gr. of 0.920 at 15°; it is only slightly soluble in cold alcohol, but is completely soluble in boiling alcohol and ether (Chem. Revue über die Fett- und Harz-Industrie, 1901, 8, 213). See also *Ucububa wax*.

Palm tree wax is the product of a palm tree *Ceroxylon andicola* (Humb. and Bonpl.), which grows on the Andes in Colombia at altitudes of 7900-9700 ft.; it attains a height of 100 ft., and the trunk is coated with the wax, which gives it a white and marble-like appearance.

The wax is obtained by cutting down the tree and scraping off the coating, which is then boiled with water; the wax is thus softened and floats on the surface, and impurities are removed. One tree is said to yield 25 lbs. The wax is made into balls and dried in the sun. Candles are made from it by the addition of a little tallow, and are sold in Carthago. That which is obtained from the Indians is yellowish-white, porous, and friable. When melted it is dark yellow, slightly translucent and fragile like resin. It is partly wax and partly resin, and melts at a temperature a little above that of boiling water; it becomes strongly electric by friction. It is readily soluble in hot alcohol; on cooling the solution becomes a white congealed mass. By using large quantities of alcohol and allowing the solution to cool the waxy part separates and the more soluble resin remains in solution; by repeating this operation several times the wax can be separated from the resin and from a small amount of a bitter substance. Ether also dissolves it, and by evaporation feathery crystals can be obtained. The purified wax melts below the temperature of boiling water, and then resembles beeswax, whilst the resinous matter melts above this temperature (Boussingault, Ann. Chim. 1825, 29, 330; 1835, 59, 19; Seemann, Pop. Hist. of the Palms, 1856, 222).

Bonastre (J. Pharm. Chim. 1828, 14, 349) obtained purified wax by repeated extractions with cold alcohol, and then dissolving the residue in boiling alcohol and filtering. When cold the solution became thick and opaque, like an aqueous starch solution; on standing for some months crystals appeared. On removing the alcohol white silky crystals were obtained; when dried and ground in a mortar it gave luminous sparks. He named this purified wax *cerosylène*, or, according to Boussingault (l.c. 1835, 59, 21), *cérosiline*. Lewy (Ann. Chim. 1845, [iii] 13, 447) found that the wax purified from the resin melted at 72°, and contained carbon 80.73 p.c., and hydrogen 13.30 p.c. Teschemacher (Mém. and Proc. Chem. Soc. 1845, 25) also describes this wax.

A wax obtained from the leaves of *Ceroxylon andicola* was examined at the Imperial Institute. It was a pale straw-coloured powder. After purification it gave the following analytical values: m.p. 93° by the open tube method, as compared with 84° for carnaúba wax, and 70°-72° for candelilla wax by the same method; sp.gr. at 15°/15° 1.018; acid value 19.8; saponification value 73.7-104.4, varying with the conditions of the experiment; iodine value 32.8. It was thought that when purified it might be used as a substitute for carnaúba wax (Imp. Inst. Bull. 1917, 15, 182, and 1919, 17, 249).

Peat wax. Waxy substances are obtained when peat is extracted with suitable solvents. By means of benzene or toluene from 1 to 8 parts of crude wax have been obtained from 100 parts of the dry material of samples from different sources. This crude wax was found to contain sulphur, usually amounting to less than 1 p.c. of the wax, but in one case reaching 30.3 p.c. The crude wax consisted of some resinous matter, but principally of a mixture of ester and free acid. The acid or acids obtained by the saponification of the crude wax corresponded in composition to a fatty acid containing

about 23 carbon atoms; the alcohols thus obtained appeared to contain about the same number. No trace of glycerides was found (Kraemer and Spilker, Ber. 1902, 35, 1212). A process was patented in 1903 by Bouchaud-Praceiq (Fr. Pat. 338736) for extracting peat, lignite, &c., with alcohol or ethyl esters, &c., and recovering the wax from the solvent. The wax is said to be hard and to resemble beeswax, and to have a higher melting-point and a sp.gr. above 1.000 (J. Soc. Chem. Ind. 1904, 23, 710).

Zaloziecki and Hausmann (Zeitsch. angew. Chem. 1907, 20, 1141), by extracting peat with alcohol, obtained a dark yellow or brown waxy substance, but the yield was only 10 grms. from some kilograms. It had no sharp melting-point, melting between 80° and 96°; it dissolved very easily in amyl alcohol, and less readily in ethyl and methyl alcohols. In ethyl ether or benzene it dissolved only partially, giving a dark green liquid and leaving a brown insoluble residue. By saponifying the substance soluble in ethyl ether an alcohol was obtained, melting between 124° and 130°, and having a composition and molecular weight corresponding to $C_{26}H_{40}O_4$, and also an acid which began to soften at 145° and melted at 184°, having a composition and molecular weight corresponding to $C_{11}H_{22}O_2$. The part insoluble in ether gave on saponification an alcohol having the same melting-point, composition and molecular weight as the other alcohol, but differing a little in its behaviour, and also an acid which had not melted when 260° was reached, and which had a composition and molecular weight corresponding to $C_{21}H_{42}O_2$. Small quantities of other substances appeared also to be present in the wax, and the above substances are very possibly mixtures.

Pisang wax. This wax occurs as an excretion on the leaves of a species of *Musa*, which grows wild in Java, especially in the uncultivated regions of Tjilatjap and Koenigian. *Pisang* is the Malay name for the banana. The natives obtain the wax by scraping the leaves, throwing the scrapings into boiling water, and then collecting the melted wax. It is said that one stem bears on the average seven leaves (a leaf may be as much as 6 ft. in length), and that 100 leaves yield $\frac{1}{4}$ kilo. of wax. The cakes of wax are white, cream, or slightly greenish in colour, and slightly transparent; the wax is hard with a coarsely granular or crystalline fracture and is very friable. It has been examined by Greshoff and Sack (Rec. trav. chim. 1901, 20, 65), who record the following: sp.gr. 0.963-0.970 at 15°; m.p. 79°-81°; acid value 2-3; it is very hard to saponify, and the saponification value found was 109. Boiling alcohol dissolves very little (about 1 p.c.), and on cooling only retains 0.2 p.c. It is easily soluble in boiling oil of turpentine, amyl alcohol, or carbon disulphide. At 15° petroleum, ether, acetone, and oil of turpentine retain 1 p.c. or less; chloroform and carbon disulphide retain less than 2 p.c. On the basis of ultimate analyses of the wax (previously freed from the part soluble in boiling alcohol), and of the acid and alcohol obtained by saponification, the authors propose provisionally the three following formulae: $C_{27}H_{44}O_2$ for the wax, regarding it as an ester formed from $C_{25}H_{42}O_2$

stearic acid, and $C_{12}H_{25}O$ pinacetyl alcohol. The acid melts at 71° , and the alcohol at 78° .

Raphia wax. The raphia palm, *Raphia pseudoculata* (Beauv.) or *Ruffia*, which grows in Madagascar, furnishes the fibrous material used by gardeners and known as 'bass'; this is the epidermis of the upper side of the palm leaf. The dull under surface is coated with a whitish layer or bloom, which can be easily rubbed off. After the bass is removed large quantities of the rapides are available as a source of the wax. They are spread out to dry on cloths in the open air, but must be sheltered from the wind as the light waxy matter is easily blown away. After drying for 2-4 days a white coating is apparent on the under surfaces of the leaves; this is detached as a powder by shaking or rubbing the leaves between the hands. The powder is collected, freed from foreign matter by sifting, and then put into boiling water when the wax melts and floats on the surface, and earthy impurities settle to the bottom. The melted wax is separated and allowed to solidify. It is yellow to dark brown in colour, and rather harder and more brittle than beeswax. In an experimental trial it was found that ten leaves of medium size ($3\frac{1}{2}$ -4½ metres in length) weighed 104.5 kilos. and yielded 0.75 p.c. of wax; the yield in practice, however, would be less than this.

Raphia wax in its physical properties resembles carnauba wax but differs chemically; it seems likely to be applicable to the manufacture of candles, polishes, &c., if it can be produced at a sufficiently low cost.

Two specimens were found to have the following properties: m.p. 82° , 83° ; sp.gr. 0.836, 0.832 at $99^{\circ}/15.5^{\circ}$; acid value 4.9, 6.5; saponification value 51.3, 50.3; iodine value 7.7, 10.7 (Bull. Imp. Inst. 1908, 6, 380). It is only slightly soluble in alcohol, ether, acetone, chloroform, light petroleum, and carbon disulphide. It dissolves, but not completely, in boiling alcohol, and separates on cooling. It appears to be mostly composed of an alcohol or mixture of alcohols having a composition corresponding to $C_{26}H_{52}O$, but differing from arachic alcohol (Compt. rend. 1905, 141, 1251; 1907, 144, 594).

In 1918 the raphia wax industry was stated to be still undeveloped, but it was believed that 10 tons would be available annually (J. Soc. Chem. Ind. 1918, 37, 240 R, from U.S. Com. Rep. Apr. 1, 1918).

Rhimba wax. In the Chamber of Commerce Journal, 1901, p. 192, an account taken from the *Moniteur Officiel du Commerce* is given of a product furnished by the Rhimba tree of Madagascar. From the description it appears to be composed of both wax and resin. The wax is said to amount to 14 p.c. The particulars about it are not clearly stated. The wax is said to resist attempts to bleach it.

Snow brush wax. The snow brush (*Ceanothus velutinus*, Douglas) is a shrub from two to six feet in height, which grows in Californian forests; it is considered a nuisance and to involve fire dangers. Scallone and Blakemore made an investigation to see if it could be utilized. Besides obtaining tannin they found that the dried leaves yielded 7.3 p.c. of wax when extracted with gasoline. The wax was greenish in colour,

owing to the presence of a little chlorophyll, and when freed from solvent was brittle with a conchoidal fracture. The crude wax gave the following analytical results: free acid 20.3; saponification number 93.4; iodine value 19.5; Reichert-Meisels number 7.5; sp.gr. at 15° 0.968; melting point 78° - 79° . From experiments made to ascertain the components of the wax, they inferred that it was probably composed in great part of ceryl and melissyl esters of palmitic and stearic acids together with hydrocarbons, free cerotic acid and a small quantity of glycerides (J. Ind. Eng. Chem. 1916, 8, 411, 573).

Spermaceti occurs in special cavities in the head of the sperm whale or cachalot, *Physeter macrocephalus* (Linn.), and also in the blubber; it is held in solution by the sperm oil at the temperature of the whale's body. It also occurs in the bottle-nose whale *Balaena rostrata*, and in some other cetaceans, but not in the oil of the whalebone whales. The spermaceti from *Balaena rostrata* has a slightly higher melting-point than that from the sperm whale. The great bulk of the head of the sperm whale consists of dense cellular tissue infiltrated with spermaceti, this is surmounted by the 'case' which holds nearly a ton of very fine oil and spermaceti known as 'head matter.' When removed this head matter is full of spermaceti crystals. The blubber surrounds the whole body in a layer about 18 ins. thick; it is 'tried down,' that is heated to separate the oil from the tissue; on cooling the oil deposits thick scales of spermaceti and becomes semi-solid. The 'trying down' is sometimes done on the ship and sometimes at the factories. At the latter the semi-solid mass undergoes several filtrations and pressings to separate the oil from the spermaceti, which is melted and cast into moulds once or twice during the series of pressings. Finally, the wax is warmed and agitated with a little caustic potash solution to remove the last traces of colour and to neutralise traces of acid, and is cast into blocks forming an almost blue-white glistening semi-crystalline solid (Field, Soc. Arts. Cantor Lectures, 1893). It is said that for some purposes it is best not to free it entirely from the sperm oil.

The sp.gr. at ordinary temperatures is about 0.945, but values as divergent as 0.905 and 0.960 have been given, owing probably to irregularities caused by the crystalline structure. The sp.gr. of melted spermaceti at 98° - 99° is from 0.808 to 0.816 as compared with water at 15° (Kahler, Amer. J. Pharm. 1897, 69, 104). The m.p. is from 41° to 49° , but by repeated purifications it reaches 53.5° . Meldrum (Chem. News, 1915, 111, 37), in order to investigate the phenomena of melting and solidifying points and the rise in temperature on setting, selected spermaceti as the substance, and records numerous experiments on it and also on the effect of impurities such as sperm oil, water, glycerin, and oleic acid. The acid value is from 0 to 1.8; saponification value from 120.4 to 124.6; the iodine value of highly purified spermaceti is 0, but values up to 0.3 (by Wijs' method) have been found, caused, as doubt, by the presence of sperm oil (Dunlop, J. Soc. Chem. Ind. 1906, 27, 63). It is insoluble in water; cold alcohol dissolves little except the adhering oil; it is soluble in boiling alcohol, ether, chloroform,

carbon disulphide; it separates in a crystalline form from the solution in hot alcohol or ether. Bohrisch and Kirschner give a long account of the examination of spermaceti for purity (J. Soc. Chem. Ind. 1921, 40, 59A, from Pharm. Zentralh. 1920, 61, 708, 719, 733).

Spermaceti is mainly composed of cetyl palmitate ($C_{18}H_{34}O_2$). It was examined by Chevreul in 1814, and the purified substance was named by him *cétine*; in 1818 he described the alcohol obtained by its saponification (now known as *cetyl alcohol*) under the name *éthol*, formed from the first syllables of ether and alcohol (Recherches, Chim. sur les Corps Gras 1839, 148). The acid with which the radicle of the cetyl alcohol $C_{18}H_{37}OH$ is combined was found later to be palmitic acid. Although spermaceti has a crystalline appearance, it contains compounds other than cetyl palmitate. Heints (Pogg. Ann. 1854, 92, 609, 93, 536) believes that it yields on saponification stearic, palmitic, myristic, and lauric acids, and the alcohols $C_{15}H_{31}O$, $C_{16}H_{33}O$, $C_{17}H_{35}O$, and $C_{18}H_{37}O$; he named the first, third, and fourth of these *stéthol*, *methol*, and *lethol* in analogy to Chevreul's *éthol*. These very probably exist in the spermaceti as esters of the corresponding acids. He also found another liquid substance in the products of saponification.

Spermaceti is used for making candles which burn brightly and in pharmacy for making ointments. For candle-making the addition of a few per cent. of beeswax or paraffin is advantageous to remove the brittleness of the spermaceti. Spermaceti candles of prescribed composition and properties were formerly used as the standard for measuring the illuminating power of different lights (Young, J. Soc. Chem. Ind. 1891, 10, 185; Met. Gas References, *ibid.* 1894, 13, 65).

Sugar cane wax. A waxy substance is produced by the sugar cane, and is noticeable on the rind of some varieties, especially near the nodes; it is most abundant on the violet cane. It was first described by Avequin (Ann. Chim. 1840, [ii.] 75, 218), who named it *cérose*. Cold alcohol removes some colouring matter, chlorophyll probably, but does not dissolve the wax. The purified wax can be obtained by removing the portion soluble in cold alcohol, then dissolving in boiling alcohol, cooling, pressing, driving off the alcohol, and melting. It is dull yellow, hard, and can be powdered; it is insoluble in water, cold alcohol and cold ether; hot ether dissolves it to some slight extent, and deposits it on cooling in small crystalline grains; boiling alcohol dissolves it completely, and the solution on cooling becomes semi-solid, just as does an alcoholic soap solution. It melts at 82° and solidifies at 80° , and its sp.gr. is 0.961 at 10° . When made into a taper it burns with a fine white flame like wax or spermaceti.

Analyses of the wax were made by Dumas (ibid. 223) and Lowy (*ibid.* 1845, [iii.] 13, 451) who assigned formulae to it on the supposition that it was a single compound, but from Wijnberg's experiments (Het Riet was en de Mogelijkheid zijner Verbranding Winning, 1900; J. Soc. Chem. Ind. 1900, 38, 991, 999) the wax appears to contain cetyl alcohol $C_{18}H_{37}O$, and also a substance with a composition corresponding to $C_{18}H_{35}O$, which is neither an ester nor a primary alcohol,

since it yields no hydrogen when heated with soda lime. Prinsen Geerligs (Arch. v. d. Java-Suikerindustrie, 1898, 1, 67) also examined the wax.

In the manufacture of cane sugar the juice is purified by treatment with lime and heating; the resulting muddy precipitate is filtered off and forms a waste product. Wijnberg proposes to extract the wax from this by the use of benzine or other solvents and utilise it (Fr. Pat. 397843, 1908). He finds that the extract from fresh mud contains a large proportion of fatty matters besides the wax, but that in mud which has been kept for some time the fatty matters undergo a kind of fermentation, and are decomposed and a product is obtained approximating more closely to the wax got by scraping the cane. It is stated that extraction of the wax has been undertaken in Java. The subject is treated of very fully in Wijnberg's book mentioned above. J. Soc. Chem. Ind. 1910, 29, 33, deals with a U.S. Patent and gives analytical values.

W. E. Cross (J. Soc. Chem. Ind. 1915, 34, 845, from Intern Sugar J. 1915, 17, 311) found from experiments that by submitting the raw mill juice to centrifugal action a product containing over 50 p.c. of wax was obtained, and this by one crystallisation from alcohol gave a pure hard product, melting at 82° .

Ucuhuba wax. An investigation of the wax from the fruit of *Myristica surinamensis*, Roland, was made by Reimer and Will (Ber. 1885, 18, 2011), who found that the chief component was trimyristin, glyceryl trimyristate. The wax obtained by an ether extraction melted at 45° . An account of the seeds of this plant, obtained from an exhibit of the Pará Province of Brazil, is given by Tschurch (Arch. Pharm. 1887, [3] 25, 619), who says that the seeds are known in commerce as *ucuhuba*. Other references are: Valenta (Zeitsch. angew. Chem. 1889, p. 3); Bolton and Hewer (Analyst, 1917, 42, 35).

About 4 tons of ucuhuba wax were exported in 1920 (Dept. Overseas Trade, Report for Brazil, 1921, p. 19). See also *Oruba wax*.

WEED KILLERS. The best weed killer for the purpose of the agriculturist is generally the hoe in some form or other, aided by the sun and wind. To permit of the ready disinfection, by mechanical means, between the crop and the accompanying weeds is one of the most important advantages of regular drilling or planting. It is only in a few cases that the farmer can derive much advantage from the application of chemical methods of destroying weeds, since, as a rule, any means which will destroy weeds, will render the soil, for a time at least, unfitted for the growth of any plant.

For destroying all vegetation, e.g. for keeping garden paths free from weeds, any general plant poison may be used. Of these there are many; indeed any soluble salt, applied in strong solution, will kill plants by producing plasmolysis. In practice, strong solutions of common salt (10 p.c., i.e. 1 lb. per gallon; dilute solution (1 part in 25 to 50 of water); dilute solutions

phenol (about 1 oz. commercial carbolic acid to a gallon of water); of sodium arsenite (about 1.5 p.c. solution); or of calcium sulphide (made by boiling 1 part of sulphur with 50 parts of water and 10 parts of quicklime) are often used, the liquid being simply applied to the surface of the walks from a watering pot, which should be well painted on the inside. Sulphides, thiocyanates, and sulphites act as effective plant poisons, and to their presence the poisonous action of fresh 'gas lime' is largely due. Many metallic salts act as plant poisons, even in excessively dilute solution. According to Coupin (Compt. rend. 1901, 654) the weakest solutions of the various salts which had an injurious effect upon the growth of the roots of the seedlings of wheat, contained 1 part of the anhydrous salt and the following parts of distilled water:—

Copper sulphate . . .	700,000,000
Mercuric chloride . . .	30,000,000
Cadmium chloride . . .	10,000,000
Silver nitrate . . .	1,000,000
Zinc sulphate . . .	40,000
Lithium chloride . . .	12,000
Calcium iodide . . .	10,000
Barium nitrate . . .	4,200
Borax . . .	1,000
Manganese chloride . . .	1,000
Calcium bromide . . .	400
Calcium chloride . . .	260

The extreme dilution of the copper sulphate, which can produce a poisonous effect, *when applied in solution to the roots*, is remarkable. In the presence of soil, however, many of these substances, including copper sulphate, are converted into insoluble and harmless compounds.

But the use of these plant poisons in agricultural practice is limited, owing to the difficulty of restricting their action to the weeds. In some countries, where a particular weed has become a scourge, recourse to these drastic measures is sometimes made, *e.g.* prickly pear in Cape Colony has been destroyed in many districts by the use of sodium arsenite, or of solutions of arsenical sheep dips, 1 or 2 p.c. solution of the former being sprayed over the uprooted plants, which then die, dry, and can afterwards be burnt.

Of more importance to the farmer is the *differential or selective* poisoning of weeds, by the use of solutions which, while destroying certain weeds, produce no injurious effect upon the crop itself. The best known of such methods is in the destruction of charlock or wild mustard (*Sinapis arvensis* [Linn.] or *Brassica Sinapistrum* [Boiss.]). The method, due to an accidental observation by Girard in France, in 1897, is to spray the barley or oat field infested with the charlock in the spring, when the charlock plants are about 2 or 3 ins. high, with from 40 to 70 gallons per acre of a 3 p.c. solution of crystallised copper sulphate, best on a still, dry, dull day. Unless rain soon follows the spraying, in which case the result is spoiled, it will be found that the charlock plants quickly blacken and die, while the barley or oats and clover (if that be also present) are uninjured. In addition to charlock, known in various districts as 'ketlock,' 'wild mustard,' 'yellow flower,' and in Ireland as 'preahagh,' other cruciferous weeds, of which

'runches' (*Raphanus raphanistrum*) is the most important, can be killed by the same treatment. Ferrous sulphate in 10 or 12 p.c. solution may be substituted for the copper sulphate, but according to experience in Ireland (Leaflet No. 6, Dept. of Agric. and Tech. Instruction for Ireland, 1901) is not so efficient. Cereals, clovers (and most other *leguminosae*) are uninjured by the treatment, but docks and thistles, although not usually killed, are seriously checked in growth.

Various explanations of this differential action of copper and iron sulphate solutions have been offered. Girard ascribed it to the solution being retained by the rough and more or less horizontal leaves of the charlock, while the smooth erect leaves of the cereals would permit of the solution running off. Against this is the fact that other plants with horizontal leaves, *e.g.* clovers, suffer little damage. Another possible explanation is that interaction between the metal of the copper or iron sulphate and the sulphur compounds which are characteristic of the *cruciferae*, may take place and lead to the destruction of the plant.

A third and probable theory is that the cell walls of the leaves of charlock are thinner or weaker than those of cereals, and more readily permit of plasmolysis being set up, when they are brought into contact with saline solutions applied to the exterior of the leaves. This view receives some support from the fact, observed by Heinrich (Jahresb. für Agricultur-Chemie, 1901, 351), that 15 or 20 p.c. solutions of sodium nitrate, ammonium sulphate, or potassium chloride—substances which cannot exert any chemical toxic effect—are also effective in destroying charlock. Moreover, the importance of a dull, still, dry day for the spraying, which is always shown in field trials, is in accordance with this explanation, for under such conditions, the droplets of the solution, deposited on the leaves of the plant, would retain their original concentration for a longer period than on windy or sunny days when evaporation would be hastened.

The experience of the Irish Department of Agriculture is that from 50 to 70 gallons per acre of a 3 p.c. solution of copper sulphate, under favourable conditions of weather, is the most effective spray for destroying charlock in cereal crops, and that even when the weed has come into flower, it can be successfully destroyed by this treatment, whilst the cereals and clover are uninjured.

Another example of differential plant-killing is afforded in the use of the so-called 'lawn-sand' for the destruction of plantains and daisies in lawns. The active ingredient in lawn-sand is usually sulphate of ammonia, and to be effective the preparation must be applied in relatively large dressings—usually about 4 oz. per square yard (= 1210 lb. per acre) is recommended. The result is that the flat-leaved plants, *e.g.* daisies and plantains, wither, turn brown and die, while the grasses, though, perhaps, temporarily injured and browned, recover and afterwards grow vigorously. Lawn-sand is generally applied in March and, after its toxic action on weeds, acts as an efficient nitrogenous manure.

A certain amount of indirect 'weed' killing can be achieved by suitable manuring; thus the

growth of grasses is favored at the expense of admitted leguminous plants, by repeated applications of nitrogenous manures, whilst the opposite effect is produced by application of calcareous, phosphatic, and potash manures with avoidance of nitrogenous ones. But this method is of limited application, and is rarely of service to the farmer. It may, however, be used in the adjustment of the relative proportions of grasses and clovers in a lawn. But for the destruction of the more important and troublesome weeds of the farm and garden reliance has chiefly to be placed upon the mechanical methods of cultivating the soil at the most suitable season. H. I.

WEINSCHENKITE. A rare mineral found in the Bavarian Oberpfaiz in white matted globular deposits and in radiating needles on brown hematite. Is mainly a hydrated phosphate of yttrium and erbium $\text{PO}_4(\text{Er}, \text{Y})_2\text{H}_2\text{O}$, containing small quantities of other rare earths (Henrich and Hiller, Ber. 1922, 55 [B], 3013).

WEHRLITE v. TETRADYMIT.

WELD is the dried herbaceous plant known as *Reseda luteola* formerly cultivated to a considerable extent in France, Germany, and Austria. Its cultivation in this country has nearly ceased, because not only is the quantity of colouring matter it contains very small, but the carriage of the plant, owing to its bulky nature, is expensive. A special interest, however, attaches to weld, for it is said to be the oldest European dyestuff known, and was used by the Gauls and other nations dwelling north of the Alps in the time of Julius Caesar.

The plant attains a height of about 3 feet, is pale brown in colour, and is sold in sheaves like straw. The colouring matter is disseminated throughout the entire plant, but the greater quantity occurs in the upper extremity and the seeds.

Luteolin, the main colouring matter of weld, was examined by Chevreul (J. Chim. Med. 6, 157; Annalen, 82, 53), who obtained it in a crude condition; its isolation in a state of chemical purity was first achieved by Moldenhauer (Annalen, 100, 180), who assigned it to the formula $\text{C}_{15}\text{H}_{10}\text{O}_6$. It was subsequently investigated by Schützenberger and Paraf (Bull. Soc. Chim. 1861, [i.] 18), who proposed the formula $\text{C}_{15}\text{H}_8\text{O}_6$ and purified it in a somewhat novel manner which is worthy of mention. Weld was exhausted with alcohol, the extract evaporated, and treated with water, which threw down a dirty greenish precipitate. This was collected, introduced with a little water into a sealed tube and heated to 250° . On cooling the sides of the tube were found to be coated with golden-yellow needles of luteolin, and the impurities had collected at the bottom of the tube to form a resinous cake.

Hasiweta suggested that luteolin had the formula $\text{C}_{15}\text{H}_{10}\text{O}_6$ and was isomeric with the paradiacetin, which he obtained during the fusion of quercetin with alkali (Annalen, 112, 169).

For the preparation of luteolin in quantity, Perkin (Chem. Soc. Trans. 1896, 69, 306, 799) suggested weld extract.

300 grms. of the extract dissolved in 3 litres of water is treated with 190 c.c. of hydrochloric acid (33 p.c.), and the mixture is digested at the boiling temperature for some hours. A quantity of a black resinous substance separates, which is collected while hot, and the filtrate, which contains the colouring matter, is allowed to stand for twelve hours. A brown precipitate of impure luteolin is slowly deposited, and is collected, washed, and dissolved in a little hot alcohol. On pouring this solution into ether, the main bulk of the impurity is precipitated, and the ethereal liquid on evaporation yields a yellow residue, which is crystallised from dilute alcohol. The product in addition to luteolin contains apigenin (Chem. Soc. Trans. 1900, 77, 131b), and the latter can only be removed with certainty by the following method:—

The mixture dissolved in boiling glacial acetic acid is treated with a few drops of strong hydrochloric acid; this causes the almost immediate separation of luteolin as hydrochloride, whereas the apigenin remains in solution. The hydrochloride is collected, decomposed by water, and the luteolin crystallised from dilute alcohol.

Luteolin $\text{C}_{15}\text{H}_{10}\text{O}_6$ crystallises in yellow needles or leaflets, m.p. $327^\circ\text{--}329^\circ$ (Perkin), 327° (v. Kostanecki, Rozycki, and Tambor, Ber. 1900, 33, 3410), soluble in alkaline solutions with a yellow coloration. With alcoholic lead acetate it gives a bright yellow precipitate and with alcoholic ferric chloride a green solution.

Luteolin sulphate $\text{C}_{15}\text{H}_{10}\text{O}_6\cdot\text{H}_2\text{SO}_4$, orange-red needles; *luteolin hydriodide* $\text{C}_{15}\text{H}_{10}\text{O}_6\cdot\text{HI}$, orange prisms; *luteolin hydrobromide*

ochre needles; and *luteolin hydrochloride*

(Perkin, l.c.), are readily prepared by the action of the acids on luteolin in the presence of boiling acetic acid. By treatment with water these compounds are quantitatively decomposed into luteolin and acid.

Monopotassium luteolin $\text{C}_{15}\text{H}_9\text{O}_6\cdot\text{K}$, fine yellow needles, from luteolin by means of alcoholic potassium acetate, is decomposed by boiling water with separation of luteolin. The sodium compound, $\text{C}_{15}\text{H}_9\text{O}_6\cdot\text{Na}$, behaves similarly.

Tetra-acetyl luteolin $\text{C}_{15}\text{H}_6\text{O}_6(\text{C}_2\text{H}_3\text{O})_4$, Perkin (also Herzog, Ber. 1896, 29, 1013), colourless needles, melts at $221^\circ\text{--}223^\circ$ (Perkin), $225^\circ\text{--}227^\circ$ (Herzig). *Tetra-benzoyl-luteolin*

colourless needles, melts at $200^\circ\text{--}201^\circ$ (Perkin).

Dibromluteolin $\text{C}_{15}\text{H}_8\text{Br}_2\text{O}_6$, yellow needles melts at 305° .

By the action of nitric acid on luteolin Rochleder (Zeitsch. für Chem. 1886, 602) obtained oxalic acid, and with fused alkali *protocatechuic acid* and *phloroglucinol*. Digested with boiling 50 p.c. potassium hydroxide solution, phloroglucinol and *acetyl-catechol* are produced (Perkin and Horsfall, Chem. Soc. Trans. 1900, 77, 1322)—

When methylated with methyl iodide luteolin yields, in addition to luteolin trimethyl ether,

also methyl-luteolin trimethyl ether (Perkin and Watson).

Luteolin trimethyl ether $C_{15}H_8O_6(OCH_3)_3$, lemon-yellow needles, m.p. 161°–163°, forms a monoacetyl derivative

colourless prisms, m.p. 156°–158°, and with alcoholic potash gives a bright yellow crystalline salt, which is decomposed by water.

On hydrolysis with alcoholic potash at 170° the trimethyl ether gives *veratric acid*, and *phloroglucinol monomethyl ether*, which was isolated in the form of disazobenzene-phloroglucinol monomethyl ether, orange needles, m.p. 251°–252°.

Methyl-luteolin trimethyl ether

melts at 191°–192°, and the monoacetyl derivative $C_{15}H_7O_6(OCH_3)_2(C_2H_5O)$ at 175°–176°. By means of alcoholic potash *veratric acid* and *methyl-phloroglucinol methyl ether* (identified as disazobenzene methyl-phloroglucinol monomethyl ether, orange-red needles, m.p. 198°–201°) are produced.

By digestion with boiling hydriodic acid *methyl-luteolin* $C_{15}H_{11}O_6$, yellow leaflets, is formed, m.p. about 307°–309°, which gives an acetyl compound melting at 235°–236°.

Perkin (l.c.) assigned to luteolin the constitution of a tetrahydroxyflavone

and the more recent synthesis of this colouring matter by v. Kostanecki, Rozycki, and Tambor (l.c.) has indicated that this formula is correct.

When *phloracetophenone trimethyl ether* is condensed with *ethyl veratrate* it gives 2:4:6:3':4'-pentamethoxybenzoyl-acetophenone

and this by long digestion with boiling hydriodic acid (sp.gr. 1.96) is converted into luteolin.

Though luteolin when digested with alcoholic potash and ethyl iodide in the ordinary manner gives only a triethyl ether, owing to the presence of an hydroxyl in the ortho position to the carbonyl group, when an excess of the reagents is employed, luteolin tetraethyl ether

colourless needles, m.p. 153°–155°, can readily be obtained (Perkin, Chem. Soc. Proc. 1912, 28, 323). Though quercetin pentamethyl ether on saponification readily gives the 6'-mononitro derivative (Watson, Chem. Soc. Trans. 1914, 105, 335), luteolin tetraethyl ether yields in similar circumstances only the *tetranitro* compound $C_{15}H_4O_6(NO_2)_4(OEt)_4$, colourless prisms, m.p. 145°. On the other hand, the introduction of only one nitro group can be effected by saponifying mono-bromo-luteolin tetraethyl ether (see below) (Perkin and Watson, *ibid.* 1915, 107, 120). Bromine (4 molecules) in acetic acid yields *bromoluteolin tetraethyl ether perbromide*

$C_{15}H_4O_6(OEt)_4Br_4HBr$, orange-yellow prisms, m.p. 161° (decomp.), and this on boiling with water gives *bromoluteolin tetraethyl ether* and *tetrabromoluteolin tetraethyl ether*.

With bromine (1 molecule) in acetic acid solution, *bromoluteolin tetraethyl ether hydrobromide* $C_{15}H_5O_6(OEt)_4Br \cdot HBr \cdot C_2H_5O$, pale yellow hair-like needles, is obtained, which when boiled with water gives *bromoluteolin tetraethyl ether* $C_{15}H_5O_6Br(OEt)_4$, colourless hexagonal plates, m.p. 183°, whereas by brominating luteolin tetraethyl ether with 2 molecules of the halogen in acetic acid solution in presence of sodium acetate, *tetrabromoluteolin tetraethyl ether*, colourless crystals, m.p. 111°–114°, is formed.

Bromo-6'-nitroluteolin tetraethyl ether

pale yellow rhombs, m.p. 170°–171°, on reduction in alcoholic solution with stannous chloride and hydrochloric acid, gives *bromo-8'-amino-luteolin tetraethyl ether*

yellow prisms, m.p. 165°–169°. This forms the *hydrochloride*

bright yellow needles, which when dried over soda lime become scarlet and melt at 187° (decomp.); with *stannic chloride* it forms the salt $(C_{15}H_8O_6NBr)_4H_4SnCl_6$, crimson prisms. By means of sodium nitrite the amino hydrochloride yields in the usual way, crystalline *bromoluteolin tetraethyl ether diazonium hydrochloride*, and from this by boiling with water *bromo-6-hydroxy-luteolin tetraethyl ether*

yellow needles, m.p. 255°, the *acetyl derivative* of which crystallises in white needles, m.p. 270°–272°, is produced.

This latter, probably owing to its insolubility, is not readily attacked by hydriodic acid (D 1.7), the first product of the reaction being apparently *bromo-6-hydroxy-luteolin diethyl ether*

the *acetyl compound* of which melts at 213°. The more drastic action of the hydriodic acid, employing also acetic anhydride, gave a small quantity of a compound crystallising in yellow needles, soluble in alkaline solutions with a yellowish brown colour, and which was probably an impure *6-hydroxy-luteolin*—

The acetyl compound melted at 250°–256°.

When air is aspirated through alkaline solutions of luteolin (and also those of chrysin and apigenin), oxidation does not occur. This property, according to Perkin (l.c.), distinguishes the colouring matters of the flavone from those of the flavonol class, which are readily oxidised by this treatment.

It has already been stated that *luteolin* contains a second colouring matter, *apigenin* (v. FANSLAY).

Dyeing properties of weld.—The importance of weld as a dyestuff in silk and wool dyeing has greatly diminished in consequence of its low colouring power compared with quercitron bark, favin, and old fustic. This in one respect is unfortunate, because, of all the natural yellow colouring matters, it yields the purest and fastest shades. In conjunction with aluminum and tin mordants it gives very bright pure lemon-yellow colours, and these do not change to an olive or reddish tint as in the case of other vegetable yellows. With chromium and iron mordants weld gives yellowish and greenish olives respectively. For yellow, wool and silk are mordanted with alum and tartar in the usual manner and dyed subsequently in a decoction of weld with the addition of chalk to the dye bath. Weld alumina yellow is to some extent still employed in this country for certain army cloths and braid. For silk dyeing, weld extract is manufactured in small quantity, and is used for the production of yellow and olive colours.

A. G. P.

WELDING (*Soude*, Fr.; *Schweissen*, Ger.) is the joining of two pieces of metal under the hammer at a sufficiently high temperature.

WELSIUM. The name given by Eder (*Akad. Wiss. Wien. Ber.* 1920, 129, 421) to an element supposed to exist between terbium and dysprosium, of which he has tabulated more than 300 lines between 36546 and 3038.

WESELSKY'S DYES v. **OXAZINE COLOURING MATTERS.**

WESTFALITES. Explosives consisting of mixtures of ammonium nitrate and resin, with or without potassium nitrate, v. **EXPLOSIVES.**

WETTER DYNAMITE, WETTEREN POWDER, v. **EXPLOSIVES.**

WHALE OIL is obtained from the blubber of various species of the genus *Balaena*, viz. *Balaena mysticetus*, Greenland or 'right' whale (northern whale oil); *Balaena australis* (southern whale oil); *Balaenoptera longimana*, *Balaenoptera musculus* (common orqual, the largest of all known animals), *Balaenoptera borealis* (northern or Rudolph's orqual) finback oil, finner-whale oil, humpback oil); *Neobalaena marginata* (Australian whale), *Rhachianectes glauca*, Cope (Japan). Other octaceans, the zoological species of which have not been determined yet, or which are identical with the foregoing species, are known as bowhead whale, Californian grey whale, orca or killer whale, beluga or white whale; these are chiefly caught by American whalers in the Northern Pacific. The northern whale oil is the 'train oil' of commerce proper; but this name has become a generic name, and has been extended to all other 'blubber oils' included in this group and even to fish oils (see **OILS, FIXED, AND FATS**).

The blubber of whales caught in the northern seas of Europe was, in the early days of the whaling industry, 'tried' on board the whalers; but in consequence of the low yield, and also of the low quality of oil thus obtained, the whales are now brought into the 'trying' stations situated in Finmarken, on the Lofotes, Faro, Shetland, Hebrides, and in Iceland.

To a large extent the American whalers still try the blubber on board ship and deliver the crude oil into the refineries of New Bedford, Mass., on the east coast, and of San Francisco

on the west coast. In British Columbia the most modern methods (see below) are now in vogue.

During recent years a very extensive whale oil industry has sprung up in the whaling grounds adjacent to the South African coast, especially to that of Natal. The whale, killed by a gun-shot, is blown up with air so as to float the carcass, which is brought immediately into the trying stations, when the whale is hoisted on to a working platform where the blubber is stripped clean from flesh, and care is taken to leave as little flesh as possible on the blubber. The latter is then cut into strips, which are thrown into chopping machines, whence the comminuted mass is immediately delivered into melting pans, and 'boiled' with steam. Five different qualities of whale oil are produced. The best quality is the oil which first runs off the blubber at the lowest temperature, known in commerce as 'Whale Oil No. 0'; it is of a pale yellow colour, and has but a faint fishy smell. This oil contains a very small quantity of free fatty acids. The best brands are 'water-white,' and are free from volatile fatty acids. On further boiling, the second quality—'Whale Oil No. 1'—runs off, it is a little darker in colour, although still pale yellow. Its fishy smell is more pronounced than the oil of the first running.

These two qualities of oil are stored in large vessels, whereby they become clarified while depositing 'stearine,' which is filtered off, pressed in hydraulic presses, and sold as 'whale tallow,' or 'whale stearine,' for soap making.

The residual mass in the boiling pans, together with the flesh of the whale, is cut up into strips or fairly large lumps, and is 'tried down' in a digester under a pressure of 40-50 lbs. The oil classed as 'No. 2 oil' is thus obtained. This oil has a brown colour and a strongly developed fishy smell; its proportion of free fatty acids is considerably higher than in 'oil No. 1'. In some stations 'whale oil No. 3' is made from the blubber residues only, and does not contain any oil from the flesh. Hence it represents a superior article to the 'No. 2 oil.'

The bones are worked up in the same manner, and yield a still inferior quality of oil. Such oil ('whale oil No. 3') is darker still, has a more strongly developed odour, and a high percentage of free fatty acids. 'Whale bone oil' of commerce is, however, not exclusively made from the bones, except in those cases where the product is sold under guarantee as 'bone oil.'

All these operations are carried out with the greatest rapidity and precision recalling the routine of the Chicago packing houses which have served as a prototype for the arrangement of a modern whaling station.

In the old whaling stations where the carcass cannot be handled so expeditiously, the oil remains for a longer or shorter time in contact with the flesh, which rapidly undergoes putrefactive changes. The oil suffers in consequence and becomes dark, and is more objectionable as regards smell and free fatty acids than the preceding qualities. This oil is known in the trade as 'carcass oil,' 'whale oil No. 4.'

The residue remaining after the removal of the oil is worked up for manure, 'whale manure.'

This process is carried out in Newfoundland (at Balena) Pacific coast, and South Africa, where the Government has established several new plants. The carcasses of the whales are there completely used up in the manufacture of oil, 'stearine,' bone meal or bones, and other articles of commerce.

If the whale is landed in a perfectly fresh state, cattle meat can be prepared from the fresh meat, as is being done in Iceland and in the Faro Islands, and in South Africa. Some fresh meat is also consumed by the inhabitants locally (Iceland and Faro Islands).

The 'right whale' oil is of better quality than the 'southern whale' oil. The 'finner whale' oil is of still lower quality. Hence the finner whale was formerly neglected by the whalers, but at present even this kind of whale is eagerly pursued by them along the coasts of Norway and Newfoundland, as also to a smaller extent on the Asiatic coast of Russia, and the coast of Japan. For the chemical characteristics of whale oil, see OILS, FIXED, AND FATS.

Doherty (J. Roy. Soc. N.S. Wales, 1922, 46, 266) obtained the following values for oils from Pacific whales: sp gr. at 15.5°, 0.9182-0.9232; n_D^{25} , 1.471-1.476; acid value, 0.75-5.8, sapon. value, 192-199; iodine value, 95-119.

The chemical composition of the whale oil fatty acids has not yet been established satisfactorily. The deposited 'stearine' consists to a large extent of palmitin. The iodine value of a sample of pressed cake examined in the author's laboratory was 37.9. Volatile fatty acids are absent. About 10 p.c. of clupanodonic acid can be isolated from whale oil in the form of its octobromide.

According to Milligan, Knuth and Richardson, who separated the fatty acids by fractional distillation of their methyl esters, a specimen of whale oil fatty acids had the following composition: myristic acid, 4.6; palmitic, 11.5; palmitoleic, 17.0; stearic, 2.5; unsaturated acids (mainly oleic), 36.5; unsaturated acids, C_{22} , 16; unsaturated acids, C_{24} , 10; unsaturated acids, C_{26} , 1.5; and unsaponifiable matter, 0.7 p.c. (J. Amer. Chem. Soc. 1924, 46, 157). E. F. Armstrong and T. P. Hilditch (J. Soc. Chem. Ind. 1926, 44, 180) found in a S. Georgia whale oil that the unsaturated acids comprised myristoleic acid, 1 to 1.5 p.c.; palmitoleic acid, 15 p.c.; oleic acid, 35 p.c.; and highly unsaturated acids with 20 and 22 carbon atoms.

Whale oil is not infrequently adulterated with resin oil, the detection of which is simple. For the recognition of seal oil reliance is mainly placed upon the taste.

The 'water-white' and 'pale' brands of whale oil are used as burning oil, and very extensively in soap-making. The lower qualities are employed for leather dressing. For the characteristics of glycerol from whale oil, see COCKS and Selway (J. Soc. Chem. Ind. 1918, 37, 126 T).

Whale oil is also used as a batching oil for putty, for tempering steel, and as a lubricant for screw-cutting machines. In the hydrogenated form (see HARDENED OILS) it is sometimes used as a constituent of margarine on the Continent. Hydrogenated whale oil yields about 0.9 p.c. of unsaponifiable matter and 0.04 p.c. of cholesterol. The unsaponifiable matter, after removal of the

cholesterol, is optically active $[\alpha]_D^{25} = +5.6$. When crystallised from acetone, whale oils yield a larger quantity of insoluble glycerides than do animal fats, and the glycerides remaining soluble in this solvent have a high iodine value (Buttenberg and Angerhauser, *Zeitsch. Nahr. Genussm.* 1919, 38, 199).

WHEAT. *Estimation of Rye Flour in Wheat Flour.*—J. König and F. Bartschat (*Zeitsch. Unters. Nahr. Genussm.* 1923, 46, 321) have thoroughly investigated chemical methods for the estimation of wheat and rye flours when present in admixture, and show that the diastase method proposed by several workers (e.g. Amberger, *Analyst*, 1922, 47, 73), methods dependent on the gluten content, on the solubility of the non-glutenous protein, or on the protein soluble in 20 to 70 p.c. alcohol are not trustworthy for the analysis of the mixed flours. It is shown, however, that the percentage of the total protein soluble in saturated solution of calcium sulphate is constant for each flour, and independent of the actual amount of protein in any particular sample of the flours. Ten grms. of the flour are moistened in a 500 c.c. flask with the saturated calcium sulphate solution at the room temperature (0.22 gm. in 100 c.c.), made up to the mark and shaken in a machine for one hour, after which the nitrogen is estimated in 100 c.c. of the clear filtrate and expressed as percentage of the total nitrogen in the flour. Treated in this way, wheat flour shows 29.1 p.c., and rye flour 51.5 p.c., so that the proportion of the two flours may be interpolated from the following table:

Wheat.	Rye.	P.c.
100	—	29.1
90	10	31.34
80	20	33.58
70	30	35.82
60	40	38.06
50	50	40.30
40	60	42.54
30	70	44.78
20	80	47.02
10	90	49.26
—	100	51.50

The average experimental error with the method is about 5 p.c., but may be exceeded in the case of flour of unusually high acidity (*Analyst*, 1924, 49, 187. See also CEREALS, vol. ii. p. 130).

A modification of Fleurent's method for the determination of the baking value of flours has been proposed by Braun (*Ann. Falsif.* 1924, 57, 269; *J. Soc. Chem. Ind.* 1924, 43, B 762). The ratio of gluten nitrogen to gluten nitrogen is used to indicate the quality of the flour.

WHEEL ORE v. **BOUENONITE**.

WHETSLATES v. **WHETSTONE**.

WHETSTONE (*Corticula*, Fr.; *Wetzstein*, Ger.), **OILSTONE**, and **HONESTONE**. Hard, fine-grained rocks, usually highly siliceous in character, used for sharpening or whetting edged tools and also for grinding metals. Rocks of several different kinds are suitable for this purpose, such as hornstone, hornfels, lydian stone, quartzite, sandstone, slate, phyllite, schist, &c. (q.v.). They must possess an evenness of grain and texture combined with a certain degree of friability. If the stone is too hard and tough to wear by friction it becomes

glassed and chipped, and does not present fresh cutting surfaces. At the same time the stone must have a certain degree of firmness and must wear evenly. The cutting power sometimes depends on the presence of minute grains of garnet, rutile, or magnetite distributed through the stone. The chemical composition of materials answering to such a description naturally varies between wide limits, but, as a rule, silica predominates. The following analyses are of I, Novaculite, 'Arkansas stone,' from Arkansas (sp.gr. 2.648). II, Novaculite, 'Ouachita stone,' from Arkansas. III, Novaculite, containing quartz and sericite, from Marquette, Michigan (also P_2O_5 , Li_2O traces). IV, Oilstone (turkey-stone) from Asia Minor. V, Belgian razor-hone from Recht (also P_2O_5 , 0.16, S 0.18, organic matter 0.02; sp.gr. 3.22). VI, Whetstone from Cambrian slates at Lausenstein, Bavaria (also organic matter 1.56).

The novaculite* of Arkansas is one of the most important whetstones. It is found over a wide area in the vicinity of Hot Springs, occurring as bands a few inches to 15 ft. in thickness, interbedded with sandstones and shales of Lower Silurian age. It has a homogeneous, finely granular structure, and is white with a faint bluish tinge. It is brittle and breaks with a conchoidal fracture; sp.gr. 2.648 (Arkansas stone). Under the microscope it is seen to consist of an aggregate of quartz grains with an average diameter of less than 0.01 mm. The stone is rendered more or less porous by minute rhombohedral cavities, representing crystals of calcite or dolomite which have been dissolved out; and it is on the presence of these cavities that the cutting action partly depends. In the trade two varieties of Arkansas novaculite are distinguished: namely, the more compact 'Arkansas' stone in which the cavities form 0.17-0.25 p.c. of the bulk of the stone; and the more porous 'Ouachita' (or Washita) stone, in which the spaces amount to 5 p.c. The latter has the dull appearance of unglazed porcelain; it is the more abundant and obtainable in larger masses, and is also more in demand. The average of several analyses shows 99.50 p.c. SiO_2 , of which 2.2-7.2 p.c. is soluble in a caustic potash solution, and 0.44-1.14 p.c. in a solution of potassium carbonate (L. S. Griswold, Whetstones and the novaculites of Arkansas, Ann. Rep. Geol. Survey Arkansas, for 1890, 1892, vol. iii.; W. C. Phalen, Oilstones of Arkansas, Min. Res. U.S. Geol. Survey, for 1911, 1912, 2, 843).

The Belgian razor-hones (anal. V) occur as

* This term is now often restricted to the Arkansas novaculite, although it was introduced by B. Kirwan in 1784 from the Latin *novacula*, a sharp knife or razor.

thin yellow bands in blue-grey slates or phyllites of Gedinian (Devonian) age, and are quarried at several places in the neighbourhood of Vielsalm and Salm-Château in the Ardennes. They are micaceous slates containing innumerable minute garnets (A. Renard, Mem. Acad. Belgique, 1876, 41). The German razor-hones from the neighbourhood of Ober-Ammergau in Upper Bavaria consist of a very compact, pale-coloured quartzose clayey limestone, and occur as beds in Jurassic limestones. They are very brittle with a splintery fracture, and are composed of $CaCO_3$, 83.57, $FeCO_3$, 2.67, clayey matter 7.63, quartz 5.96=99.85 (C. W. Gumbel, Geogn. Beschreib. Bayern, 1861, 1). The celebrated Turkey oilstone (anal. IV) is also calcareous, containing SiO_2 , 70-75, $CaCO_3$, 20-25 p.c., with often a little alumina. It is obtained in the interior of Asia Minor and exported from Smyrna. Two varieties are distinguished, the white and the black, the latter being slightly the harder.

In England several stones of a more or less similar character are obtained at various places; e.g. the Charley Forest stone or Whittle Hill hornstone, which is a fine-grained, siliceous, slaty rock worked in Leicestershire. The Welsh oilstone is a somewhat similar material from near Llyn Idwal in North Wales. Devonshire oilstones are obtained from the metamorphosed slaty rocks in the neighbourhood of Tavistock. From Scotland come the Water-of-Ayr stone, snake stone, and Tam o' Shanter hones.

The coarser grained scythe stones are made of certain kinds of sandstone. Those from Pike in New Hampshire are the most celebrated, being exported to all parts of the world. This material is a fine grained, thinly laminated, micaceous sandstone (W. C. Phalen, The scythe-stone industry in New Hampshire, Min. Res. U.S. Geol. Survey, for 1909, 1911, 2, 616). Scythe-stones have been long worked near Blackdown in Devonshire, and are known as 'Devonshire batts.' They are made from siliceous concretions embedded in sand, probably of Upper Greensand age. Similar scythe-stones are also made at Penzlewood, near Stourton in Wiltshire.

In preparing whetstone for use, the blocks as quarry dressed are sawn into small rectangular slabs with a lapidary's disc charged with diamond powder, and then smoothed down on an iron plate charged with emery. Tools for special purposes, as used by dentists, engravers, watchmakers, jewellers, &c., are ground to the required shape.

Wheels made of Arkansas stone are used for fine metal grinding; and powdered whetstone is used as an abrasive material by instrument makers. See also ABRASIVES.

WHEWELLITE. Hydrated calcium oxalate $CaC_2O_4 \cdot H_2O$, crystallised in the monoclinic system. It forms small, water-clear crystals which are often twinned in heart-shaped forms resembling those of calcite. There are perfect cleavages, and the material is very brittle; sp.gr. 2.46; $H=2\frac{1}{2}$. The refractive indices and double refraction, $\alpha=1.4900$, $\beta=1.5552$,

$\gamma=1.6497$, $\gamma-\alpha=0.1597$, for sodium-light, are very nearly the same as those of calcite (viz. $\epsilon=1.4962$, $\omega=1.6585$, $\omega-\epsilon=0.1713$). The crystals could therefore be used for the construction of Nicol prisms for polarising apparatus, if only they were found of sufficient size or if such could be produced artificially. The mineral is found in coal mines, but at only a few localities, namely, Burgk and Zwickau in Saxony, and Brûx and Schlan in Bohemia. It occurs, together with calcite, dolomite, barytes, &c., in small fissures in the shales and sometimes in the coal itself. Crystals have also been found in a metalliferous vein with tetrahedrite and ankerite at Urbeis in Alsace, and under similar conditions at Freiberg in Saxony. L. J. S.

WHISKEY. The term 'whiskey,' applied to the national beverage of Scotland and Ireland, only came into common use in the latter part of the eighteenth century, and is derived from the Celtic 'uisque-beatha' or 'usquebaugh,' meaning 'water of life,' no doubt in reference to its stimulating properties. A similar signification is seen in the terms applied to strong alcoholic liquors in other countries, as 'aqua vitæ,' and 'eau de vie.' Burns employs the three terms 'aqua vitæ,' 'usquebaugh,' and 'whiskey' synonymously.

The introduction of the manufacture of alcohol into Europe is, as the word suggests, due to the Arabs, but in the grape-growing countries of the south, the spirit is naturally produced chiefly from wine, and in the north, from different kinds of grain, the different materials used giving rise to the distinctive flavours characteristic of the spirits of different countries.

In Scotland the manufacture of whiskey was a subject for legislation as early as the sixteenth century, and extracts from the statutes show that 'aqua vitæ' was not the exclusive product of malted barley, but that unmalted grain was also used in the early days of spirit distillation in Scotland, and this has been the practice in Ireland up to the present day.

In 1803, during the Napoleonic wars, and owing no doubt to the possibility of a shortage in the supply of grain for food, the use of grain for the manufacture of spirits was prohibited throughout the United Kingdom.

In both Scotland and Ireland the pot-still was used prior to the invention of the patent continuous still by Aeneas Coffey in 1831, since when the patent still has been increasingly employed for the manufacture of spirit from a mixture of malt and unmalted grain, and known locally as 'whiskey.' About two-thirds of the potable spirit made in Scotland and Ireland at the present time is of this description. The spirit produced from other materials as molasses, rice, starch, potatoes, dates, currants, &c., is almost invariably distilled from a 'patent still,' and is used chiefly for industrial purposes. When malt only is used the whiskey is produced in Scotland chiefly, and in Ireland exclusively, from pot-stills. At the present time (1926) there are 9 distilleries in England; all of which are patent-stills only. In Scotland, out of 124 distilleries, 9 use patent-stills and 115 pot-stills only. In Northern Ireland, only 4 distilleries are at present working, and of these 2 use patent-stills and 2 pot-stills only. In the Irish

Free State, out of 14 distilleries, 3 use patent-stills, one both patent and pot-still, and the remainder pot-stills only. Of the latter, 10 are at present 'silent,' i.e. not working.

In 3 of the distilleries in England, 6 in Scotland, and 2 in Northern Ireland, yeast is manufactured on a large scale as a commercial product. In some instances, yeast is the principal product of manufacture—the spirit produced at these distilleries being really a 'by-product.'

The different characters of the various kinds of whiskey are due to the presence of small amounts of secondary products, sometimes referred to as 'impurities' or 'by-products' (as esters, higher alcohols, &c.), rarely exceeding in the aggregate one-half p.c. of the ethylic alcohol present, but sufficient to impart a distinctive flavour and aroma to the spirit.

These differences in character depend mainly upon (a) the kind and relative proportions of the materials used in the mash; (b) the methods of mashing and fermentation employed; and (c) the type of still used and the manner in which it is worked.

For the processes of mashing, fermentation, and distillation employed in the manufacture of ordinary alcohol, and for a description and diagram of Coffey's patent still, see article ALCOHOL.

This is known as 'silent' or neutral spirit, but grain spirit, distilled from patent stills, when intended for potable purposes, is not so highly rectified as to be deprived of its 'whiskey' character.

In the manufacture of pot-still whiskey in Scotland, barley-malt is practically the only material employed in the mash, whilst in the Irish pot-still distilleries the mash consists of a mixture of barley-malt with unmalted barley or other grain. The proportions vary with a view to securing particular flavours in the whiskey, but a typical mash consists of about four-fifths barley (malted and unmalted), and one-fifth of wheat, oats, and rye, the proportions decreasing in the order of enumeration. Maize is generally excluded from the pot-still whiskeys.

Besides the formation of sugar by the action of diastase during the mashing process, other substances, the exact nature of which is not thoroughly understood, are obtained in solution, from which the secondary constituents of the finished whiskey are both directly and indirectly derived. According to Bell (Select Committee of the House of Commons on British and Foreign Spirits, 1890-1) some of the essential oils naturally existing in the malt and grain, and the empyreumatic and creosotic bodies with which the malt becomes impregnated during the process of drying over peat, anthracite, or coke fires, pass through the operations in a more or less chemically unchanged condition, thus imparting distinctive characters to the whiskey, particularly when the ordinary pot-still is employed for the distillation.

Similarly during the process of fermentation, the conversion of the sugar into ethyl alcohol is accompanied by other chemical changes resulting in the formation of substances which also influence the flavour of the finished whiskey. Of these the principal are the higher alcohols,

which have been shown by Ehrlich and others to be due to the splitting up of certain nitrogenous substances (amino acids) produced by the peptonising action of the malt in the mashing process. The ultimate result is affected by the special nature of the yeast, the temperature at which it works, and the time occupied in fermentation.

The simplest form of pot-stills employed in Scotland are heated by direct fire, and have no special means of rectification. The long neck of the still, however, although originally designed simply to prevent particles of the boiling mash being mechanically carried over by frothing or spraying, incidentally has the further important practical use of effecting considerable rectification.

The pot-stills sometimes have their rectifying power increased by means of perforated plates placed transversely in the neck of the still, or by the use of 'purifiers,' pipes or circular vessels cooled by water and fitted between the neck of the still and the condenser.

Some stills are heated by means of steam-jackets or coils instead of direct fire, and this difference in the method of heating is said to have an important influence on the flavour of the whiskey. Certain empyreumatic bodies are thought to be generated by the open fire method, but according to Bell, Schidrowitz, and Thorpe, these are more probably derived from the peat or coke used for heating the malt kilns.

In the manufacture of Scotch whiskey, two distillations only are usually made, first from the 'wash still' from which the whole of the volatile constituents are collected as 'low wines'; and second, from the 'low-wines still,' the distillate from which is collected in three fractions, viz. (1) 'foreshots,' (2) clean spirit or 'whiskey,' and (3) 'feints.' The first and third fractions are added to the low wines of the next distilling period, and so on throughout the distilling season, the residue left in the wash still ('pot ale'), and that in the low-wines still ('spent lees') being run to waste.

The whiskey is generally run off at a strength of 11-25 overproof, but in the Lowlands, where a third distillation or 'rectification' is generally made, the strength of the whiskey distillate is from 40 to 54 overproof.

In Ireland the pot-stills are generally much larger than in Scotland, having sometimes a capacity of 20,000 gallons. The head of the still is shorter, and the still for low wines and feints is provided with a 'lyne arm,' or long pipe which passes through a tub of water, the liquid thus condensed between the head of the still and the worm being conveyed by a 'return pipe' to the body of the still. By this means a considerable degree of rectification is effected.

Three distillations are the rule for Irish pot-still whiskey, and the fractions are more numerous than in the manufacture of Scotch whiskey, consisting of strong low wines, weak low wines, strong feints, and weak feints. The middle or 'whiskey' fraction is also run off at a higher strength than in the Scotch process, viz. from 24 to 30 overproof.

The point at which the collection of foreshots is stopped and that of whiskey commenced, as well as that at which the running of whiskey ceases and the collection of feints begins, is determined by the judgment and

experience of the distiller, but various simple devices are employed for testing the distillate at different stages, as glass floats or hydrometers, specific gravity beads, and samplers for testing the distillate by dilution with water and observing whether the mixture is opalescent or clear.

Scotch whiskeys may be divided into the following five principal classes: (1) Highland malts; (2) Lowland malts; (3) Campbeltowns; (4) Islays; all made from malt in pot stills; and (5) grains, a name given to patent-still whiskeys. *Irish whiskeys* have no corresponding classification, all the 'self' or non-blended whiskeys being sold under distinctive names.

The secondary products, and therefore the character of the spirit, are considerably affected by the strength at which the whiskey is run off. Some of these products (especially esters) suffer partial decomposition in both the wash and low wines stills, whilst others, of higher boiling-point, remain in the stills and are run to waste with the pot ale and spirit lees. More than two-thirds of the secondary products are lost in this manner, only from 10 to 30 p.c. passing into the finished whiskey. (For the recovery and utilisation of the esters left in still residues, see art. RUM.)

It has not yet been found possible to trace any definite relationship between the commercial characteristics of various pot-still whiskeys and their composition as ascertained by analysis, for the reason that the secondary constituents are not individually identified by chemical analysis, but are assessed in groups consisting of members of the same family though in varying proportions, e.g. acids, aldehydes, esters, and higher alcohols.

There is some reason to believe, from the researches of Guareschi and Mosso (on behalf of the Italian Government), Vaughan of Michigan University, and Husz of Sweden, that other bodies may be present due to decomposition of albuminous matter in the grain and having alkaloid properties. They are alleged to be largely accountable for the deleterious effects of spirit drinking, but, if present, they occur in such minute quantities as to elude identification hitherto.

Husz attributed the unusually deleterious character of the spirits drunk in Sweden in a certain year to the use of unsound grain, and Lombroso has shown that an alkaloid having an action like strychnine is generated in decaying maize. Lauder Brunton, whilst attributing much of the harmful effects of new spirit to furfural, also supports the theory that these effects may be partly due to the presence in minute quantities of alkaloidal bodies, especially in potato spirit.

Schidrowitz has determined the percentage of nitrogen in new pot-still whiskeys with the results shown below, but failed to detect the least trace of substances giving alkaloidal reactions. The nitrogen is calculated as NH_3 , and expressed as grams per 100 litres of absolute alcohol—

Highland malts	0.09-0.12
Lowland malts	0.11-0.20
Campbeltowns (malt)	0.08-0.14
Grains	0.03-0.14
American rye whiskeys (matured)	0.25-0.30

No definite evidence was, however, obtained by the Royal Commission on Whiskey, &c., that the deleterious effects attributed to the consumption of spirits are directly due to the presence of poisonous secondary products, and the bulk of the medical evidence was to the effect that the actual amount of the secondary products is so small compared with that of the ethyl alcohol, that the physiological effects produced by them must also be extremely small in comparison with those due to the ethyl alcohol itself. It would appear to follow, therefore, that whiskey derived either from pot or patent still has much the same toxic effect if taken in the same quantity and at the same alcoholic strength.

At the same time, since many substances are known to produce marked effects on the digestive system merely as a result of the sensation produced by their *flavour*, this plays an important part from a dietetic point of view, and the more agreeable flavour of a mature whiskey may exert a favourable mental effect which promotes the

activity of the digestive processes, whilst the unpalatable flavour of new 'silent' or neutral spirits may tend to interfere with digestion apart from the direct effect due to the alcohol itself.

The methods usually employed for the estimation of the different groups of secondary constituents are given in detail in the Minutes of Evidence taken by the Royal Commission on Whiskey and other Potable Spirits, 1908-9, vol. ii. App. Q. xii. Thorpe; see also vol. i. App. F. Schidrowitz.

The following tables give the results of analyses of various kinds of whiskey by Schidrowitz, Tatlock, and Thorpe, expressed in all cases as parts by weight in 100,000 parts by volume of absolute alcohol (e.g. grams per 100 litres).

Schidrowitz and Kaye's results of analyses of 100 samples of the principal classes of *Scotch pot-still whiskey* are summarised in the following table, showing the minima, maxima, and averages—

No. of samples	Description	Total acid	Esters	Higher alcohols (A-M)	Aldehydes	Furfural	Average total 'Impurities'

Results of analyses of 5 samples of spirits made in Germany and sold as cheap whiskey in Hong Kong are given on p. 466.

Samples A and B consisted of 'silent' spirit, with an admixture of pot-still whiskey for the purpose of imparting the genuine flavour of whiskey. They are very similar to what is usually sold as 'whiskey' in public houses in England. Samples C, D, and E consisted of highly rectified 'silent' spirit coloured and flavoured to imitate whiskey. The fusel and impurities were much less than is usually found in genuine Scotch and Irish pot-still whiskeys of high commercial quality, while furfural and other aldehydes were practically absent, and there was no evidence that the spirits contained anything of a deleterious nature apart from the alcohol itself.

'Pot-still' and 'patent-still' spirits (Thorpe, Royal Comm. on Whiskey and other Pot-still Spirits, App. Q. vi., vii., viii.). "An examination

secondary constituents in the 'pot-still' spirit. Speaking generally, the percentage of every one of the secondary constituents usually determined is greater in the 'pot' than in the 'patent' spirit, but the most marked differences are in the 'higher alcohols' and 'furfural.' 'Patent' spirit contains no furfural when new, although after storage in wooden casks it is sometimes found to contain traces of this substance, but always in much smaller amount than in 'pot-still' spirit, in which it is never absent. The low percentage of the 'higher alcohols,' and the absence of all but mere traces of furfural render it a comparatively easy matter to distinguish 'patent' from 'pot-still' spirit. But the variations in the amounts of the secondary constituents in both classes of spirits renders it less easy to estimate the exact proportion of each kind of spirit present in mixtures. Comparing the 'pot-still' spirits among themselves, it will be observed that there are considerable variations in both the total amount and in each constituent of the secondary bodies. The Scotch whiskeys generally show a somewhat less total amount than the Irish, and the Speyside, Banffshire, and Highland samples have a rather smaller amount than the Islay and Campbeltown samples. The latter, as well as most of the Irish samples, are mainly 'blending' as distinguished from 'self' whiskeys.

The differences between new and old 'pot-still' whiskeys, so far as shown by analysis, are mainly in the increased amounts of the volatile acids and aldehydes, and to a less extent of the esters found in the old spirit when stored in wooden casks. The higher alcohols and furfural appear to remain very much the same. Any changes that occur in 'patent' spirit are of a similar kind.

'Pot-still' whiskey is almost always stored in cherry casks, or in other well-seasoned wooden casks that have formerly contained similar spirit. A large proportion of the increases in the secondary constituents which occur in spirit stored in such casks takes place in the first few months, and is due to a process of extraction of these products absorbed in the wood of the casks from former spirits. This

absorption is to some extent selective. The ethyl alcohol slowly diffuses through the wood of the cask and passes into the air, leaving some of the esters and higher alcohols behind in the wood, which thus becomes more or less charged with the secondary constituents, according to the length of time and other circumstances attending the storage of spirit in the warehouse.

Probably also, especially when the casks are empty, there is some production of acids, aldehydes, and esters by the slow oxidation of alcohols in the wood of the casks.

A comparison of the ordinary 'patent' spirits with British and foreign spirits of high strength which are not usually stored in wooden casks, but in metal drums or vats, shows that the latter spirits contain still less of the secondary constituents, and that the slight changes which occur in ordinary patent spirits do not take place in these high strength spirits. These spirits are used mainly for technical and industrial purposes, and are often of very great purity, although made from molasses, potatoes, and beetroot sugar residues, or other materials not employed for making spirits intended for consumption in this country.

Maturation or ageing.—In addition to the changes above referred to in the secondary constituents due to storing in casks, there are other changes due to the presence of substances not included in the ordinary analysis of spirits, but which have much to do with the difference in flavour of new and old whiskeys. Thorpe, for example, found indications of pyridine bases, allyl alcohol, and allyl aldehyde derived from the peat used as fuel in malting, and acrolein, due either to the fat in the wash extracted from the grain or possibly from the soap which is occasionally added to the contents of the still to prevent frothing. Schidrowitz found in new pot-still whiskey distinct evidence of the presence of pyrrole, phenolic bodies, an alkaline substance (probably an ammonium salt), sulphuretted hydrogen, sulphurous acid, and a trace of nitriles. All of these are readily changed on exposure to air and moisture, as in storage in casks. The pyrrole probably resinifies, the phenols interact with aldehydes, acids, and

alcohols, forming condensation products; the sulphuretted hydrogen and sulphurous acid would readily oxidise, and the nitriles (if present) rapidly condense or be transformed into acids. None of these substances was found in mature spirit.

Numerous processes have been suggested for the artificial ageing or maturing of whiskey. These are, for the most part, oxidation processes, as by treatment with charcoal, or (as in Carroll's process) by passing the spirit vapour mixed with air, and superheated to 300°F. through a pipe enclosed in a steam jacket also heated to 300°F. Hewitt's method, which is a de-aldehyding process, consists of the addition of phenylhydrazine-sulphonate of sodium or calcium to the low wines still, by which means the aldehydes, including furfural, are held back, and the amount of these passing into the distillate considerably reduced. The effect of all these processes is to remove the harsh flavour of new spirits and impart the softer character of mature whiskey, thus accelerating the time when the spirit becomes ready for consumption as a beverage, but without necessarily imparting to it the true characteristic flavour of whiskey which has been matured by long storage.

The changes in the secondary products due to storage of whiskey in wooden casks and bottles are shown by Thorpe in Appendix Q. ix., x., xi. The results show that there is a well-marked increase in each of the secondary constituents during the first six months' storage. After 9-12 months the higher alcohols and furfural remain practically constant, and the increases in the other constituents were very slow. After about 18 months the differences were within the limits of experimental error. Practically no change occurs in spirits stored in glass bottles.

Crampton and Tolman (J. Amer. Chem. Soc. 1908, 30, 98) examined the spirit stored in casks by sampling annually for a period of 8 years,

and found an increase in the higher alcohols due to the fact that the wood was less pervious to these than to ethyl alcohol and water. The other secondary constituents increased rapidly for 3 or 4 years, and then only very slowly. An increase of furfural was probably due to the charred wood of the interior of the casks. It was found also that water passed through the wood of the cask more rapidly than the ethyl alcohol, thus giving rise to an increase in strength. This is unusual and was no doubt due to the exceptionally warm and strongly ventilated place of storage.

American whiskey.—The United States Pharmacopœia prescribes the following requirements for whiskey. It should be at least 2 years old; its sp.gr. should lie between 0.930 and 0.970; its alcoholic content should be not less than 44 p.c., nor more than 55 p.c. by weight; its residue not more than 0.25 p.c.; the residue from 100 c.c., which should be neither sweet nor spicy, should dissolve in 10 c.c. of cold water, and this solution should be coloured only a pale green when treated with a drop of very dilute ferric chloride solution (a deeper colour would indicate more than traces of tannin). In evaporating the liquor on the water-bath for the residue, the last traces volatilised should have an agreeable odour free from harshness, indicative of the absence of fusel oil. Its reaction should be slightly acid, but not more than 1.2 c.c. of deci-normal alkali should be required to neutralise 100 c.c. of the liquor using phenolphthalein as indicator.

Rye whiskey is made in the United States and Canada from rye and malt only. *Bourbon whiskey* (so-called from Bourbon County, Kentucky, where it was originally made) is prepared from a mixture consisting of 50-60 p.c. maize, 10 p.c. malt, and the remainder rye.

The following table gives the results of analysis of Bourbon and rye whiskeys by Schudrowitz:—

Description	Total acid	Esters	Higher alcohols (A-M)	Aldehyde	Furfural	Total

Results of analyses of 188 samples of new and old Bourbon and rye whiskey examined in the laboratory of the United States Department of Agriculture (Wiley) are shown on next page.

Imitation whiskey is sometimes prepared from strong neutral or 'silent' spirit diluted to the proper strength and flavoured with certain essential oils or artificial fruit essences, as oil of wintergreen, cinnamic and pelargonic esters, and coloured with caramel. Prune juice is sometimes added to give 'body' to this mixture.

Fleischman quotes the following as a recipe for a low grade 'blended whiskey': spirits, 32 gallons; water, 16 gallons; caramel, 4 oz.; beading oil, 1 oz. 'Beading oil' (so-called from its use in producing an artificial bead on cheap liquors) is prepared by mixing 48 oz. of sweet oil of almonds with 8 oz. of commercial sulphuric acid, neutralising with ammonia, adding double the volume of proof spirit, and distilling the mixture (The Art of Blending and Compounding Liquors and Wines, New York, 1885).

Adulteration of whiskey.—Under Sect. 10 of the Licensing Act, 1921, whiskey (like brandy and rum) may not be sold below a strength of 35 p.c. under proof unless the fact of dilution is notified, and the great majority of prosecutions under the Act for the adulteration of whiskey are on account of dilution with water below the legal limit of strength. For the method of calculating the degree of dilution, see art. BRANDY.

Sometimes a neutral or 'silent' spirit made from substances other than grain (as potatoes, beet-sugar residues, &c.) is mixed with sufficient genuine whiskey to give it a more or less whiskey character, and such adulteration is best detected by expert tasting ('degustation') combined with a determination of the secondary constituents and a comparison of the relations which they bear to each other.

Amongst the various substances alleged to have been used for the grosser forms of adulteration may be mentioned creosote, fusel oil,

methylated spirit, sulphuric acid, and salt. Traces of copper, tin, and lead have been found as accidental impurities derived from the stills and other apparatus employed.

In consequence of representations made as to the deleterious character of the whiskey sold in public-houses in the poorer class districts of the larger towns in England, Scotland, and Ireland, and at fairs and markets, particularly in the west of Ireland, an investigation into the matter was made some years ago by the Excise Authorities. Nearly 100 samples were taken from all parts of the United Kingdom and analysed in the Government Laboratory, but, apart from the fact that most of these consisted mainly of plain patent-still spirit, no evidence of the presence of the deleterious adulterants above referred to could be found.

The results of analyses (showing the maxima, minima, and averages) are summarised in the following table (Thorpe):—

	Volatile acid	Alde- hydes	Esters	Higher alcohols	Furfural	Total
England (38 samples)—

Average	8.2	11.1	47.8	232.0	1.2	300.3

There is no legal definition of 'whiskey' in the United Kingdom, but numerous suggestions were made by witnesses before the Select Committee on British and Foreign Spirits in 1890-1, and the Royal Commission on Whiskey and other Potable Spirits in 1908-9, differing

essentially in principle and depending chiefly upon the point of view of the witness.

The strictest definition suggested was that 'whiskey' should be manufactured in a pot still exclusively and from certain prescribed materials grown in the country, as malted barley alone in

the case of 'Scotch' whiskey, and malted barley with unmalted grain (barley, wheat, oats, or rye) in the case of 'Irish' whiskey.

Others would admit patent-still spirit, restricting, however, the materials to cereal grains (including maize), and the saccharifying agent to the diastase of malt, whilst in a few cases the extreme view was held that no restriction should be imposed either on the materials used or the process of distillation.

Since much of the barley used in both Scotland and Ireland is of foreign growth, the definition of Scotch and Irish whiskey cannot well exclude the use of foreign grain, and therefore maize (which came into use in 1846 immediately after the repeal of the Corn Laws) is not excluded in the manufacture of 'whiskey.'

With respect to the blending of patent-still spirit made from grain with pot-still spirit, it was held that since whiskey (consisting as it does of alcohol and water, with certain by-products derived from malt and grain) does not cease to be whiskey when diluted with water, so the addition of patent still spirit, also made from grain, does not remove the mixture out of the category of 'whiskey.'

After full consideration of all the evidence the Royal Commission of 1908-9 arrived at the following conclusions and definitions:—

(1) That the term 'whiskey' having been recognised in the past as applicable to a potable spirit manufactured from (a) malt, or (b) malted and unmalted barley or other cereals, the application of the term 'whiskey' should not be denied to the product manufactured from such materials.

(2) That no restrictions should be placed upon the processes of, or apparatus used in, the distillation of any spirit to which the term 'whiskey' may be applied as a trade description.

(3) *Definition*—'Whiskey' is a spirit obtained by distillation from a mash of cereal grains saccharified by the diastase of malt, that 'Scotch whiskey' is whiskey, as above defined,

distilled in Scotland; and 'Irish whiskey' is whiskey, as above defined, distilled in Ireland.

WHITE VITRIOL. *Zinc sulphate $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ v. ZINC.*

WHITING v. CHALK.

WILKITE A rare mineral consisting of tantalic and titanic acids, zirconia, silica, cerium, and yttrium earths, thorina, uranic oxide, ferrous oxide, &c., and of interest in containing scandium (Sc_2O_3 , 1.17 p.c.) in relatively large amount. It is a black, brown, or yellow, amorphous mineral resembling euveitite or yttriotantalite in appearance, and has been found, together with monazite, in a felspar quarry at Implaks, Lake Lagoda, Finland. It supplied the material for Crookes's work on scandium (Proc. Roy. Soc. 1904, A, 50, 516, Phil. Trans. 1908, A, 209, 15). Orthite from the same locality has also been found to contain 0.8-1.0 p.c. of scandia (R. J. Heyen, Sitz. Ber. Akad. Berlin, 1911, 379). More recently, a mineral containing scandium as an essential constituent has been described (r. THORTVALLITE) L. J. S.

WILD RICE. A comparison between wild rice (*Zizania aquatica*) and cultivated rice gave the following analyses for wild rice:—

No.	Moisture. p.c.	Ash. p.c.	Protein. p.c.	Ether Extract. p.c.	Fibre. p.c.	Starch p.c.	Soluble carbohydrates as dextrose. p.c.
1	7.74	1.09	13.36	0.46	1.39	65.26	2.98
2	7.85	1.38	13.97	0.89	1.41	61.69	3.69
3	8.93	1.17	14.62	0.72	1.94	60.47	2.33
4	7.83	1.25	14.40	0.66	1.29	62.03	2.93

Although these results show a high proportion of proteins in wild rice, both these and the mineral salts present are of a variety unsuitable for dietetic purposes. There is just sufficient vitamin A to prevent xerophthalmia, but not enough to promote growth. Wild rice is somewhat superior to the cultivated variety as regards its content of vitamin B, but still is not an adequate food (C. Kennedy, J. Agric. Res. 1924, 27, 219; Analyst, 1924, 49, 342).

WILKITE v. THORTVALLITE.

WILLEMITE. A mineral consisting of zinc orthosilicate Zn_2SiO_4 , crystallising in the rhombohedral system (with parallel-faced hemihedrism). It is abundant at Franklin Furnace,

and Sterling Hill in New Jersey, where it is mined, together with zincite and franklinite, as an ore of zinc (Zn 55.5 p.c.). Here it is usually massive, but a few clear prismatic crystals of a pale amber-yellow colour, and up to 6½ cm. in length, have been found. Some of these have been cut as gem stones. Portions of the better coloured or clearer massive material is also suitable for cutting as gems. The mineral has also been found at a few other localities, but only in sparing amounts. It varies considerably in colour, being yellowish, apple-green, flesh-red, &c.; the lustre is vitreous to resinous; sp.gr. 4.0-4.1; H. 5½. Troostite is a variety containing up to 10 p.c. of MnO replacing the zinc

oxide, and found as large rough crystals at Franklin Furnace. When struck with a hammer or when exposed to the emanations of a radium salt, the mineral displays a brilliant green phosphorescence. Crystals of willemite have been obtained artificially, and have also been observed in slags and in the muffles of zinc furnaces.

WILLEDSEN FABRICS AND PAPER v. CELLULOSE.

WILLOW BARKS v. TANNING.

WILLYAMITE v. ULLMANNITE.

WINE. Wine, strictly speaking, is the fermented juice of the fruit of *Vitis vinifera*. The term *British wines* is applied to beverages made after the manner of wine from substances other than the juice of fresh grapes.

The vine is cultivated for the manufacture of wine in the middle and south of Europe, the northern and southern extremities of Africa, some of the western parts of Asia, the islands of the Atlantic, portions of America—from the Potomac in the north to the centre of Mexico in the south—in California, and in Australia. The number of varieties is very large; but experience shows that the vines employed in particular districts should either be indigenous to those districts or be improved varieties of the indigenous strain. Thus, European vines when tried in America were but partially successful; whilst, on the other hand, American vines transplanted to the Gironde degenerated and yielded no potable wine. The vine grows on chalky, silicious, aluminous, and magnesian soil, best along the borders of rivers, and on ground which, though not itself soaked with water, can constantly attract it from the sub-soil.

Vintage and vinification.—The methods of procedure vary with the character of the wine—i.e. whether white or red wine is to be produced. The practice as regards the period of ripeness at which the grape is gathered varies considerably; thus, in the case of champagne, where the greatest attainable paleness is desired, the grapes are gathered before the point of fullest maturity, whereas the wines of Burgundy are vintaged when the grapes produce the deepest colour. Wines from imperfectly-ripened grapes require longer time to mature after manufacture, and, theoretically speaking, the grapes should hang until excessive dryness or danger of frost threatens; but other and conventional considerations, such as colour, have to be taken into account. In exceptional instances, as in the Sauterne district, those berries only are cut out of the bunch which have attained the desired point of ripeness; but the common practice is to gather all the grapes carried by the vines, the vintagers either separating immature and spoiled berries as they proceed, or carrying the whole bulk to a kind of specialist, who performs this part of the labour. Whichever course may be taken, the selected fruit is carried to the press house, and the question then arises whether the stalks are to be removed or pressed with the grapes. In the case of white wines the almost universal practice is to leave the grapes upon the stalks, for the reason that the resulting liquor is almost at once separated from the marc, and before the astringent principle of the stalks can be communicated to it, whereas red wines must be allowed to remain upon

the marc for some time, and the stalks are removed. The commonest mode of separation is to cause the grapes to pass through a series of sieves, by which the stalks are retained. The grapes are now crushed, either by being trodden underfoot in vats or by being passed through machines furnished with grooved rollers, the one thing to be avoided in either case being the bruising of the seeds and stalks if these have not been removed. The next process is pressing. The machines employed for this purpose were formerly boxes, so made that the must was expelled through apertures by superincumbent pressure exerted by a screw; but latterly centrifugal machines have been employed, with a saving of labour and time. In white wines the must is separated as much as possible from the marc before pressing; whilst in the preparation of champagne the grapes are not crushed at all previous to being placed in the press. In pressing grapes for the manufacture of champagne the pressure is so regulated that the juice is separated into four fractions; generally, 4000 kg. of grapes yield a first fraction (cuvée) of 20 hectolitres of juice, second and third fractions of 3 hl. each, and a fourth fraction of 2 hl. The first fraction is the most valuable and yields a wine containing a relatively higher quantity of total acids and free acids (tartaric and malic acids); the presence of these acids increases the resistance of the wine to 'sickness' and to the action of bacteria. The keeping qualities of the wine are also due to the fact that only very small quantities of nitrogenous substances, phosphates, and potassium salts are present. The other fractions of the juice are less valuable, and the wines prepared from them are more readily attacked by micro-organisms (E. Manceau, *Ann. Falsif.* 1923, 16, 517; *J. Soc. Chem. Ind.* 1924, 43, B. 227). According to L. Mathieu (*Chimie et Industrie*, 1923, 10, 847), white wines are liable to the same causes of turbidity as red wines, but the effect is more marked, as a slight haze, imperceptible in a coloured wine, completely destroys the limpidity of the colourless wine. The author classifies turbidity—under which heading he includes all degrees of haze, from the pale bluish fluorescence due to the most minute particles, to actual cloudiness with visible particles—under two headings: (1) normal, i.e. arising in the actual constitution of the wine, such as bacterial infection, cloudiness caused by chilling or heating, or by oxidation of resinous substances or the mutual interaction of the constituents of the wine, and (2) accidental, i.e. caused by some irregularity or oversight in the manufacture or manipulation. As in the case of other wines, one of the most fruitful causes of trouble is the presence of iron in more than insignificant traces. This may arise from the use of unprotected iron vessels. The rigid exclusion of iron vessels, unless the metal be protected in some way from the attack of the acids of the fruit, is essential (*J. Inst. Brewing Abstr.* 1924, 30, 234). In the case of red wines the colour is obtained by allowing the juice from the crushing to ferment, after which it is stirred with the grape husks, whereby the requisite amount of colouring matter is dissolved. So much of the must as can be drawn off by this is run off by that means, and the marc is pressed

the two portions of the must are then added together. The proportion of must depends upon whether the stalks are removed or not; in the former case it is about 95-97 p.c. of the whole, in the latter it may only be 70 p.c.

The following is a summary of analyses by König of a large number of musts of different origin:—

	Specific gravity	Water	Nitro- genous p.c. matter	Sugar	Acid	Other non-nitro- genous matter	Ash
Minimum	1.0690	51.53	0.11	12.80	0.20	1.08	0.20
Maximum	1.2075	82.10	0.57	35.45	1.18	11.62	0.63
Average	1.1024	74.49	0.28	19.71	0.64	4.48	0.40

Fermentation.—The natural fermentation of grape juice is due to the action of various yeasts (*Saccharomyces Ellipsoideus*, *S. Pastorianus*, *S. Marzianus*, &c.) existing on the skin of the grape, and to 'Zymæ' and other enzymes present in the juice. Sergeant and Rougebief (Compt. rend. 1924, 178, 732; J. Soc. Chem. Ind. 1924, 43, B. 207) have drawn attention to the dissemination of grape yeasts by insects. They concluded from their experiments that certain insects, particularly *Drosophyla*, play an important part in spreading the yeast. White wines are generally fermented at a temperature of 10° or 12° in barrels with only the bunghole open for the escape of carbon dioxide. Red wines are generally fermented in vats open at the top, on account of the bulk caused by the retention of the husks and the necessity of stirring, an operation variously performed during or at the completed period of fermentation, according to the district. The higher the temperature the sooner the fermentation is finished; at low temperatures a moderate fermentation takes place, which becomes more violent as the liquid becomes warmer, and reaches a maximum at 27°. By the employment of high temperatures a must rich in sugar can be converted into a wine feebly alcoholic, sweet, and yet having tasting properties. Medium musts are best fermented at from 20° to 24°, and this temperature is reached when the fermentation begins at 15°. When fermentation is completed—i.e. after 10 to 14 days—the liquor has become clear, the yeast cells and other suspended matters are deposited at the bottom of the vessel, and the 'young' wine is racked off and allowed to rest for some weeks.

The young wine slowly loses its sugar by after-fermentation, and albuminous substances, colouring matters, together with the acid potassium tartrate, and calcium tartrate, separate out, forming a crust known as *argol* or *argal* (q.v.; also TARTARIC ACID). It is then racked again into clean casks (which are often 'sulphured' before use), fined, if necessary, with isinglass or white of egg, and occasionally with dried blood or with potassium ferrocyanide. When clear it is racked again and sometimes pasteurised before being bottled or stored in casks to mature.

Influence of the 'marc' on wine.—By allowing the skins and stones of ripe grapes to remain in contact with the must, the resulting wine is said to improve in bouquet, &c., and is less liable to become stale and rosy. In order to redden wine with the skins of black grapes the temperature of the wine should be between 15° and 17°. Bad grapes impart to white and red wines a brown colour. Such wines soon become

turbid. Bad grapes and mildewed skins, as well as bad casks and puncheons, precipitate the red colouring matter, so that the wine becomes pale. The following are some of the cases in which the treatment of wine with 'marc' has been successful: Wine which is muddy and cannot be clarified by the ordinary fining agents; wine in which a fining agent has been used which failed to sink to the bottom; wine which has become weak and flat; wine which is assuming or has assumed a black colour; wine having a barrel taste or a by-taste; wine which is 'corked'; wine remaining after casking off; and wine which is obtained by pressing the lees. In cases where the fermentation of new wine has been checked suddenly, the addition of marc prevents the separation of yeast (J. Nessler, Chem. Zentr. 1882, 265; Chem. Soc. Abstr. 1882, 1014). Wines from pressed marc have a greater content of extract, tannin, ash, total and ammoniacal nitrogen, phosphoric acid, sulphate, and chloride than wines from the vat (Hugues, Ann. Falsif. 1925, 18, 347; J. Soc. Chem. Ind. 1925, 44, B. 936).

Composition.—Wine contains alcohols, glycerol, acids, salts, extractive matter, and those principles which give to it its particular colour, special flavour, smell, or bloom (*bouquet*, *Blume*). Whilst some of the constituents can be accurately isolated and described, others can only be detected by the smell.

The principal alcohol is ethyl alcohol. In rare instances some butyl alcohol, and in others amyl alcohol, together with ethylene glycol and isobutyl glycol (Henninger) are present. The quantity of alcohol in natural wines from grapes varies from 6 to 12 p.c. by weight, or from 13 to 26 p.c. proof spirit, but these limits are extended in exceptional cases. The quantity of glycerol is usually from 7 to 14 p.c. of the alcohol present.

The principal acids present are tartaric, malic, and tannic acids, due to the original grape juice, and carbonic, formic, acetic, and succinic acids as products of fermentation. These greatly aid in the preservation of the wine by preventing the formation of fungi. Traces of propionic, butyric, and cœnanthic acids also occur in wine, together with acetaldehyde and possibly some of its homologues. Salicylic and boric acids have also been found as natural constituents of wine. As regards the origin of the fixed vegetable acids of wine, H. Brunner points out (Chem. Zentr. 1877, 4) that malic, succinic, glycollic, and oxalic acids—which are found in unripe grapes, together with tartaric acid—may either be formed by direct building up of the molecules in the plant, or their formation may be partly direct and partly indirect.

Tartaric acid occurs mainly as the dextro-variety; lævo-tartaric acid is only of comparatively infrequent occurrence. If tartaric acid is not found—as, for example, in certain samples of sherry—its absence is probably due to its removal by 'plastering,' to which reference is made later on. The amount of free acid in sound wine, reckoned as tartaric acid, varies between 0.3 and 0.7 p.c. (inclusive of volatile acid, which should not exceed 0.15 p.c.); a greater amount than this imparts sourness to the wine.

It can be demonstrated in the laboratory that the first reduction products of carbonic acid are formic and oxalic acids, and that, from the latter, we can (by the action of hydrogen) pass successively through glyoxylic, tartaric, and malic, to succinic acid, and all these acids have been found in the grape in its various stages of growth. The principal reactions may be represented as follows:—

The characteristic smell of wine is said to be due to enanthine and other esters. These esters probably confer the bouquets which distinguish one vintage from another. Among them are acetopropyl, butyl, amyl, capryl, butyro-ethyl, caprylo-ethyl, capro-ethyl, and pelargo-ethyl, and the tartaric esters.

According to Jacquemin (Compt. rend. 110, 1140), the characteristic bouquets of wines are due to the special characters of the yeast used in each district. One and the same must fermented with the yeast obtained from several different districts gave wines having the bouquet characteristic of the district from which the particular yeast had come.

Babo states that the bouquet of the wine from Riesling grapes is produced by the action of frost; wines from other grapes also possess a like bouquet if the grapes are frozen. Rommer (Bull. Soc. chim. [iii.] 2, 297) fermented the juice of an inferior grape and of hot-house grapes respectively with yeast cultures obtained from the Champagne, Côte d'Or, and Baxy districts, and found that in each case the wines had the bouquet of those from which the yeast has been derived. Certain of the odoriferous principles are no doubt in the nature of essential oils, which have not hitherto been isolated owing to their small amount and extremely unstable character under the influence of heat and air. In order to retain the bouquet, wines should be bottled as soon as they have attained their maximum bouquet.

According to Berthelot, the amount of the esters in wine is, after a certain time, a constant quantity independent of the nature of the alcohols and acids, but a function only of their relative amount: If A be the percentage weight of alcohol in the mixture, a the amount of alcohol equivalent to the total free acid contained in one litre of wine, on the assumption that it is acetic acid (46 alcohol = 60 acetic acid), y the proportion p.c. of a present as ester in one litre of wine when the alcoholic strength of the wine is A , and x be the amount of alcohol present in the compound esters of one litre of wine; then

$$y = 1.17A + 2.8$$

$$x = \frac{y \times a}{100}$$

The alcohols other than ethyl alcohol present

are left out of the account, but as they are insignificant in amount the error is trifling. This formula affords a mode of judging of the age and genuineness of wines, except in the case of very young wines, or wines which have been recently fortified, the esters in these cases being less than that required by the formula. The maximum esterification is reached in from 4 to 6 years. The alcohol obtained by the decomposition of all the esters rarely exceeds 0.06 p.c. of the wine. (For Thudichum and Dupré's method, v. their Treatise on Wine, 203.)

Sugar in wine.—The sugars occurring in must and in wine are dextrose and levulose. Cane sugar is never naturally present in must, but it is sometimes added, as in the case of champagne, but even then it is rapidly transformed into invert sugar. Glycerol is formed as a by-product of the growth of yeast during the process of fermentation, and is accompanied (amongst other changes) by the decomposition of sugar. For every 100 parts of sugar which disappear, from 3 to 4 parts of glycerol are produced. After complete fermentation the sugar seldom reaches 0.5 p.c., but when fermentation is arrested by the addition of alcohol, as in the liqueur wines of France and Spain made from dried grapes, and the sweet wines of Hungary, the sugar may be as much as 20 p.c. or more. In some wines—as e.g. Sauternes and sweet Rhine wines—sugar occurs in the form of inositol.

The colouring matters in wine are due to two sources. In white wines—which range from an almost colourless liquid, as champagne, to the deep yellow sherry—the colour is derived from the oxidation of the so-called extractives contained in the juice, which, as was before explained, is separated from the husks as quickly as possible. The grapes of some of the best red wines yield an almost colourless juice if pressed before fermentation, and it is only by the joint action of alcohol and acid upon the husks, stalks, and seeds during fermentation, that the red colour is extracted from the marc. Mulder separated the colouring matter contained in red wines by means of lead acetate, and found it to consist of a substance which was bluish-black in colour and amorphous in structure. It is only sparingly soluble in alcohol, insoluble in water, ether, chloroform, carbon disulphide, oil of turpentine, oil of olives; but soluble in solution of tartaric acid or cream of tartar, and in alcohol containing a trace of acetic acid, the saturated solution showing a blue colour; more acetic acid turns the solution red. It is soluble also in alcohol containing tartaric acid, exhibiting a red colour, but neither of these acids renders it soluble in ether or chloroform. The colour of wine, consequently, depends both upon the amount of colouring matter and the amount of free acid contained in it, as the violet colour becomes redder in proportion to the quantity of free acid acting upon the blue colouring matter.

The colouring matter precipitated by hydrochloric acid—in which it is deposited slowly at the ordinary temperature, but more rapidly on boiling—has been examined by Terrell (Bull. Soc. chim. [ii.] 44, 2). The precipitate always contains a substance resembling ulmic acid, from which the colouring principle may be dissolved

out by alcohol. Thus obtained it forms brittle varnish-like scales, insoluble in water and ether, but readily soluble in alcohol, forming a brownish-red solution with a slightly yellow tinge. Acids change this colour to an intense red, while alkalis give a green coloration, which changes rapidly to a brownish-yellow on exposure to the air (cf. O. Griessmayer, *Dingl. poly. J.* 123, 531; *Chem. Soc. Trans.* 1887, 368).

The generally held view that the browning of wines is due to unsound grapes is not correct. The presence of stalks in the fermenting mash contributes appreciably to browning. Very acid wines are particularly prone to browning. The browning is most probably due to the oxidation of tannin-like substances of phenolic character by the action of oxidases or by auto-oxidation, or probably by both processes. It can be prevented, at least to a considerable extent, by immediately pressing the grape mash, but this course is not always possible in practice (H. Müller-Thurgau, A. Osterwalder, and H. Haller, *Landw. Jahrb. Schweiz*, 1923, 37, 215; *Chem. Zentr.* 1923, 74, [iv.] 1010; *J. Soc. Chem. Ind.* 1924, 43, 109).

The browning of wines, which is not only accompanied by a discoloration, but also with a strong turbidity and an unpleasant flavour, can be arrested by the use of sulphur dioxide in the form of potassium metabisulphate, which is added to the juice in the cask before fermentation. The yeasts can withstand without risk quantities of sulphur dioxide towards which *Bacterium gracile*, which effects the decomposition of malic acid at the close of the fermentation, is sensitive. The inhibition of the decomposition of the acid, whether it be temporary or complete, is mainly dependent on the quantity of free sulphur dioxide. Further, the duration of time during which the sulphur dioxide remains in the free condition must be borne in mind, as combination proceeds at different rates with different juices, and therefore the action of the same quantity of sulphur dioxide is not always identical. The commencement of the decomposition of the acid is, moreover, influenced not only by the number of acid-decomposing bacteria present, but also by the nature of the juice and its chemical composition, e.g. the content of tartaric acid. From very extensive experiments it was found that the addition of 2-4 grms. of $K_2S_2O_5$ to a hectolitre did not in any case hinder the decomposition of the acid. With 5-6 grms. inhibition was produced with juices rich in tartaric acid, and by the addition of 7.5-8 grms. of $K_2S_2O_5$ to different juices a slight retardation was observed. Quantities of 10-14 grms. of $K_2S_2O_5$ per hectolitre, corresponding with an initial content of free sulphur dioxide of 28 mg. and more per litre, produced complete inhibition of the decomposition of the acid (H. Müller-Thurgau, A. Osterwalder, and H. Haller, *Landw. Jahrb. Schweiz*, 1923, 37, 241; *J. Soc. Chem. Ind.* 1924, 43, B. 109).

The colouring matter of red wines may be estimated with sufficient accuracy for technical purposes by the method of Cari Mantrand (*Bull. Soc. chim.* 1906, [iii.] 35, 1017), by precipitating with lead acetate, decomposing the precipitate with sulphuric acid, filtering, and weighing the residue from an evaporated portion of the

filtrate. The extracted colouring matter may be concentrated and preserved in glycerol for use in confectionery, &c. The maximum amount found was 17.2 grms. per litre in Algerian wine.

According to Willstätter and Zollinger (*Annalen*, 1915, 408, 83; 1916, 412, 195) the colouring matters of wine, viz. *oenidin* and *oenin*, are derivatives of delphinidin. *Oenidin*, which has been isolated from the black Italian grape, is the dimethyl ether of delphinidin, and *oenin* is the monoglucoside of *oenidin*.

The pigments present in two varieties of American grapes, namely, Norton (*Vitis aestivalis*, *V. labrusca*) and Concord (*V. labrusca*), have been examined by the methods of Willstätter and Zollinger (*Annalen*, 1915, i, 295; 1917, i, 47). The same anthocyanin chloride, $C_{28}H_{22}O_{11}Cl_3H_2O$, has been isolated from both varieties. On hydrolysis, it yields dextrose and an anthocyanidin chloride, $C_{17}H_{14}O_6Cl_3H_2O$. The substances are identical in composition with the *oenin* and *oenidin* chlorides obtained by Willstätter and Zollinger from European grapes (*V. vinifera*), but they differ from these substances in that the anthocyanidin contains only one methoxyl group, whereas *oenidin* contains two. The colour reactions are, moreover, different. The anthocyanin gives with ferric chloride in aqueous solution a purple colour which quickly fades to light brown, and in alcoholic solution an intense blue which changes to purple and finally to wine-red; the anthocyanidin gives with the same reagent both in aqueous and alcoholic solution a momentary purple colour fading to an almost colourless or faintly yellow solution. Evidence of the presence of a diglucoside has also been obtained (R. J. Anderson, *Bio-Chem. J.* 1923, 57, 795; *J. Chem. Soc.* 1924, 126, i, 251).

Some additional colour is imparted to white wine by the tannin extracted from the oak casks during maturing. On the other hand, the natural colouring matter of red wine is reduced by the operation of fining as well as on ageing.

Caramel is frequently used to colour white wines (e.g. brown sherry), and occasionally boiled must is added either to the juice before fermentation or to the finished wine. (For foreign colouring matters, see below.)

Tannin is derived from the grape skins and stalks, the juice itself being practically free. It is sometimes added, however, to champagne and other white wines to prevent 'scuddiness' or turbidity. The natural tannin of grapes is decomposed by acids or by fermentation into glucose and an acid which is not gallic acid.

The *albuminous substances* in the grape, which set up the ferment, ought by that action to be removed in the yeast when the fermentation is properly carried out, and should not exceed 4 parts per 1000 of wine, unless the latter has been 'fined.' The albuminous matter is also reduced by 'plastering,' and in old wines it is thrown out together with tannin and colouring matter. In imperfectly fermented wines a certain amount remains, and, in the case of white wines, may again render them liable to fresh fermentation. In red wines this danger is obviated by the presence of the tannin of the

husks, which preserves the albuminous matter from change.

The small quantity of ammonia which is present in grape juice, or is formed during fermentation out of albuminous substances, is, for the most part, precipitated during fermentation as magnesium-ammonium phosphate; a small amount, however, remains, and in some wines is accompanied by minute traces of trimethylamine.

Under the term 'extractives,' some chemists include all matters other than water, alcohol, and volatile acids; others only those substances which are not volatile up to 100° or 110°. The latter would, however, exclude glycerol, which is properly included amongst the extractives. The composition of certain constituents of the extract which contribute to the smell and taste of the wine is still very obscure. The extractives are, of course, abnormally increased by plastering and addition of sugar (*v. infra*).

The mineral constituents of wine, as found in the ash, are potash, soda, and lime as phosphates, chlorides, carbonates, and sulphates, traces of iron, magnesia, and silica, and occasionally alumina, lithia, and manganese. In pure natural wines the ash rarely exceeds 0.3 p.c., but may be much higher in wines which have been plastered, or to which alkalis have been added to reduce their acidity.

As regards the amount of alcohol, a very comprehensive set of tables, embracing the results of the examination of 133 wines, is given by Thudichum and Dupré (Treatise on the Origin, Nature, and Varieties of Wine, 128-304), from which the following résumé is compiled:—

	Strength of wines in degree of proof spirit
German wines, 35 samples	16.2-26.3
French wines, 22 samples	18.0-36.2
Spanish wines, 22 samples	26.7-47.7
Sicilian wines, 6 samples	35.5-31.3
Portuguese wines, 14 samples	21.9-46.5
Hungarian wines, 10 samples	19.2-22.4
Greek wines, 8 samples	17.8-36.1
Cape wines, 7 samples	36.1-52.7
Atlantic Islands, 3 samples	38.2-31.1
Elbe wines, 1 sample	34.99
Australian wines, 5 samples	23.5-40.1

Sugar solution wines.—Musts which are too thin, and deficient in sugar, are sometimes concentrated by evaporation (as in Portugal) or, more frequently, a solution of sugar is added. The latter process was first sanctioned by the French minister, Chaptal, and is known as 'Chaptalising.' A similar process (applied chiefly to acid musts), and known as 'Gallising,' from its inventor Gall, is also practised in Germany. The must of bad years, which contains a deficiency of sugar and an excess of acid, is mixed with sugar, preferably cane sugar, so as to bring the amount of sugar in the liquid to about 20 p.c., and to reduce the amount of acid to about 2 p.c. Frequently, however, commercial glucose is used, and its addition can frequently be detected in the finished product by its dextrorotatory polarisation (*cf.* Fresenius and Grünhut, *Zeitsch. anal. Chem.* 1921, 60, 188).

The acidity of natural wine can also be

reduced, as suggested by Liebig, by the addition of neutral potassium tartrate, which throws down the free acid, if present as tartaric acid, as acid potassium tartrate. Wine deficient in alcohol and containing much acid may often be improved by adding to it the pressed residue of a succeeding vintage (*cf.* J. Nessler, *Bied. Zentr.* 1884).

A considerable quantity of wine is now made by covering the marc with an aqueous solution of sugar, and allowing the mixture to ferment. The sugar solution contains 18 grms. per litre for every degree of alcohol which it is desired to obtain, and 250 grms. of marc are used for each litre of solution. Analyses of wines prepared in this way by Girard, and of other samples found in commerce, prove that these wines have an approximately definite composition. When they contain from 9 to 10 degrees of alcohol, the proportion of soluble matter, cream of tartar, tannin, and colouring matter is much less than in the ordinary vintage wines. The amount of solid matter varies from 14 to 18 grms. per litre; the amount of cream of tartar is about 2 grms., but not less than 1.6 gm. per litre; whilst the proportion of tannin and colouring matter varies considerably with the nature of the marc. Girard concludes that those wines constitute a highly useful beverage, and can be produced at a very low cost (*A. Girard, Compt. rend.* 95, 227; *Chem. Soc. Abstr.* 1882, 1335).

Plastering of wine.—The practice of adding gypsum or plaster of Paris to must, either before or after fermentation, which prevails in Spain, Portugal, and the South of France, is said to have for its object the reduction of the amount of the water in the juice, and the production, consequently, of a must relatively richer in sugar. The fermentation is much more rapid and complete, and it is alleged that the wine keeps longer when it has been plastered, and that the colour is richer and more lasting. This explanation leaves something to be desired, because the sacrifice of other constituents of juice than water due to absorption by plaster is entirely out of proportion to any gain by the absorption of the water, and the result desired could be attained either by the addition of sugar or the evaporation or freezing out of water. It is probable that the reason for the practice, although unknown to those who employ it, is that gypsum precipitates some albuminous matters which injuriously effect the wine. An obvious advantage to the wine-maker is that it clarifies the wine rapidly and so enables it to be brought sooner to market.

The plaster of Paris, in the form of powder, is either thrown upon the grapes before they are crushed, or added to the must after fermentation has commenced, or even to the finished wine, and the chemical changes that take place vary accordingly. The quantity used is generally from 1 to 2 kilos. to every 100 kilos. of fruit, although sometimes it reaches as much as 10 kilos.

According to Griessmayer, when gypsum is added to the must, it forms, with the tartar present, neutral calcium sulphate and free tartaric acid, which latter reacts on the sulphate, forming bitartrate and acid calcium sulphate. According to Borntraeger (*Annali. Chim. Applic.*

1919, 12, 1), the reaction between calcium sulphate and potassium bitartrate is as follows:

It was shown by Bussy and Baignet that the system ($\text{K}_2\text{SO}_4 + \text{C}_4\text{H}_5\text{O}_6$) is converted into $\text{KHSO}_4 + \text{C}_4\text{H}_5\text{KO}_6$. The ash of such wine is neutral, and does not give off carbon dioxide when treated with hydrochloric acid. When gypsum is added to the finished wine, the alcohol prevents its solution, but it carries down many impurities. Kayser (Bied. Zentr. 1881, 632) made experiments which confirmed these conclusions, and states that from the proportions of the ash to the extractive matter, it is possible to declare with certainty whether the wine has been plastered as must or as finished wine; in the first case the ash is disproportionately high, in the other it remains normal. Kayser also states that by the interaction of KHSO_4 and KH_2PO_4 , free phosphoric acid is formed together with neutral potassium sulphate, the former producing the bright colour of plastered red wines. The main change, however, appears to be a decrease in the tartrates and an increase in the proportion of potash and sulphates.

The injurious effects attributed to plastered wines have been the subject of investigation by several commissions appointed by various foreign governments. The most exhaustive inquiry yet made on the hygienic aspect of the subject was by a commission appointed by the French War Department owing to complaints made by the French army in Algeria, where many cases of illness were said to be due to the use of plastered wines. The symptoms are said to be colic, and slight vomiting. The acid potassium tartrate acts towards many reagents in the same manner as free sulphuric acid, and when introduced into the system may have the effect of reducing the alkalinity of the blood.

In view of the inconclusive nature of the evidence, the Commission recommended the maintenance of the regulation forbidding the sale of wines containing more sulphate than that corresponding with 2 grms. of potassium sulphate in the litre, and this limit has been also adopted in Germany, Switzerland, and other countries.

The attempts to 'de-plaster' wine are, from a hygienic point of view, more injurious than the plastering, owing to the use of poisonous barium and strontium salts.

Wine is liable to be affected by a number of injurious ferments, and is especially subject to acetous fermentation, due to *Mycoderma aceti*, which principally attacks the alcohol with production of acetic acid, whilst *Mycoderma vini* attacks principally the cream of tartar and extractive matters. The action of foreign ferments may frequently be prevented by the process devised by Pasteur, which consists in heating the wine for some time to about 70° in absence of air. The bouquet, and in some cases the colour, is thus found to be improved. The heating must be quickly performed, and, as far as possible, out of contact with air.

Numerous substances are employed for the preservation of wine by chemical means as *abramol* or *aseprol* (the calcium salt of β -naphthol sulphonic acid), benzoic, boric, and cinnamic

acids, fluorides, formaldehyde, saccharin, salicylic acid, sulphurous acid, and sulphites. It should be noted that of these, boric acid, fluorine, and salicylic acid may be present in minute quantities as natural constituents of the wine (*v. infra*).

Sulphuring is carried out either by burning sulphur, sometimes placed on strips of paper, linen, jute, asbestos, &c., in the casks, or by addition to the wine of sulphurous acid or one of its salts. For small works the use of aqueous sulphurous acid or potassium metabisulphite, $\text{K}_2\text{S}_2\text{O}_5$, is most convenient, and in large works that of liquid sulphur dioxide. The colouring matter of red wine is at first bleached by sulphur dioxide, but with proper sulphuring the wine later assumes a more vivid red colour than the non-sulphured wine. In the wine the sulphur dioxide is converted partly into sulphuric acid and into compounds with acetaldehyde and dextrose, the rest remaining in the free state—sulphites are blood- and stomach-poisons, but they are readily and rapidly changed in the human body. Most German wines contain less than 200 mg. of total or 50 mg. of free sulphur dioxide per litre, but with choice wines, which require repeated sulphuring to bring their slow fermentation to a close, as much as 546 mg. per litre has been found; similar results are obtained with sweet sauternes (Journ. Soc. Chem. Ind. 1923, 285 A.). According to Dubaqué, the clouding of white wines after keeping in glass bottles may be due to the action of sulphur dioxide in the wine upon iron silicates of the glass (Ann. Falsif. 1925, 18, 418; J. Soc. Chem. Ind. 1925, 44, B. 821).

The essential oil of black mustard seed (b.p. 150-7°C.) is soluble in alcohol and ether, but in water only to the extent of 1.16 grms. per litre at 15°C. Its antiseptic power, when used in wines, is such that 1 c.c. of a 1 p.c. solution added to 1 litre of wine is efficient, but the amount required varies with certain factors, such as the amounts of sugar and sulphurous acid in the wine, the quantity and vitality of any yeasts present, and the temperature. The souring of red wines, which generally contain no sugar, can be stopped by the addition of 0.8 c.c. of the 1 p.c. solution above mentioned. Essential oil of mustard is about 200 times as active as sulphurous acid and does not affect the odour or flavour of the treated wines. It does not volatilise from the wine, and therefore does not require to be renewed. It has no action on the colouring matters of red wines, fruit juices, caramel, etc. It is estimated by heating 5 c.c. of the preservative on a water bath for 1 hour, with 10 c.c. of ammonia solution and 55 c.c. 0.1N silver nitrate solution in a graduated 100 c.c. flask connected with a reflux condenser. The solution is cooled, diluted to the mark, filtered from the precipitate, and the silver estimated volumetrically in 50 c.c. of the filtrate (P. Malvezin and G. Bidart, Ann. Falsif. 1923, 181, 534; Analyst, 1924, 49, 140; cf. Moreau and Vinet, Ann. Falsif. 1924, 17, 477; J. Soc. Chem. Ind. 1925, 44, B. 49).

Manufacture of 'sparkling' wines.—The effervescence of a sparkling wine is due to the presence of carbonic acid, produced by the fermentation of added sugar. The chief wines of this class (champagne) are produced in the departments of Marne and Haute-Marne, and in

the vicinity of the Moselle and the Rhine. Both white and red grapes are used, and the wine is amber in colour, the depth of tint depending on the vintage and the proportion of dark grapes employed. The vintage is in the early part of October, and in the pressing the must is separated into two portions, that first produced being of the higher quality. The young wine is allowed to ferment until the winter, when it is racked, and after the expiration of a month the operation is repeated, when the wine is fined. It is then mixed with a certain proportion of old wine, and the amount of sugar present determined. If necessary, a quantity of cane sugar is added, and the wine is bottled, the bottles being placed horizontally in piles and left at rest throughout the summer. Carbonic acid is formed, together with a quantity of sediment. The pressure of the gas in the bottles can readily be ascertained, when desired, by means of a manometer (such as Salleron's modification of Maumené's 'Aphrometre'), and ranges from 5 atmospheres in *grand mousséux* to less than $4\frac{1}{2}$ in *crémant* wine; in ordinary *mousséux* wine the pressure varies between 4 and $4\frac{1}{2}$ atmospheres. When required for the market, the bottles are first carefully brought into an inclined position, so as to cause the sedimentary matter to fall gradually on to the cork; on removing the clip which holds the cork within the neck the pressure of the dissolved gas forces out the cork, together with the sediment. A certain amount (from 1 to 4 p.c., depending upon the sweetness desired) of liqueur, made of fine wine, sugar, and cognac or a still spirit, is quickly added, and the bottles are again filled up, corked, and wired.

Dry champagnes—i.e. containing relatively little sugar—are mainly exported to this country, the sweeter varieties being usually consumed in America and on the Continent.

Wines of France. The pre-eminence of France as a wine-producing country is due mainly to its favourable conditions in regard to both climate and soil, and, no doubt, also to the system of small holdings worked by the thrifty and industrious French peasantry. The chief wine-growing district in France is the Gironde, which is practically divided into five portions, viz., the Médoc, the Graves, the Côtes, the Palus, and the Entre-deux-Mers. To these must now be added the wines from the Alsace-Lorraine territory restored to France by the Treaty of Versailles. Although formerly retained almost exclusively for home consumption, they are now (1926) obtainable on the British market. In the Médoc some six or seven different varieties of vine are cultivated.

Most of the *red wine* is obtained from the Carbenet Sauvignon, Franc Carbenet, Malbec, and Merlot grapes. The vintage usually begins towards the end of September, and lasts about a fortnight. The wines (usually known as 'claret') are divided into *payean*, *artisan*, *bourgeois*, and *fine growths*, the last group being further sub-divided into what are known as 'crus' or 'classified growths,' named after the place (Château or Commune) where they are produced; e.g. *Château Latour*, *Pauillac*; *Château Lagrange*, *St. Julien*; *Château Margaux*; *Château Cantenac*, &c. The official classification into 'crus' or 'growths' was made so long ago as 1855 by the *Chambre Syndicale des Courtiers*,

since when it has not been found necessary to make any alteration. (*Vide* 'Bordeaux et ses Vins,' by Feret, Bordeaux, and *Encyclopædia Britannica*; art. 'WINE.')

The chief *white wine* producing district is to the south of Bordeaux. The principal vines are the Semillon, Sauvignon, and Muscatelle. The vintage is much later than in the Médoc—viz. in the last weeks of October or early part of November, when the grapes have entirely ripened. Three qualities of must are produced: the first and ripest juice yields a sweet luscious wine (*vin de tôle*), mainly consumed in Russia; the second forms *vin de milieu*, the wine usually known as *Sauterne*; the third quality, or *queue*, yields a dry white wine. The principal varieties are *Barsac*, *Sauterne*, *Graves*, and *Bommes*, *Château Latour-blanche*, and *Château Yquem*, which is generally considered to be the premier white wine of France, if not of the world, and in the classification of Sauternes it takes precedence of the 'First Growth,' being placed in a class by itself.

The department of the Pyrénées Orientales produces a considerable quantity of wine, mostly from the Grenache noir and Carignane grapes. The generic name of the wine of the district is *Roussillon*, of which the most esteemed varieties are muscat of *Rivesaltes*, *Maccabeo*, *Mulvoisie*, and *Grenache*, which are liqueur wines (the last-mentioned being simply unfermented must preserved by means of added spirit and sulphurous acid, with frequent racking from deposits); and *Rancios*, dry *Mulvoisie*, and *Picfoule*. Languedoc also produces a large quantity of wine (*vins du Midi*), much of which is mixed with the wines of the Gironde and of Burgundy: whilst a considerable amount of the rest is distilled to make 'trois-six' and *eau de vie*. Cognac is produced from the wines of the Charente district (*v. BRANDY*).

The Rhône and Saône valleys produce the chief wines of the east of France, which, with the exception of *Hermitage* and the wines of the *Beaujolais*, seldom occur in trade under their own names.

The best qualities of *champagne* (*v. supra*, *Sparkling wines*) are produced in the departments of Marne and Haute-Marne, the chief centres of the trade being at Rheims, Épernay, Ay, Avize, Châlons, and Dizy. The most famous brands are *Ayala*, *Bollinger*, *Cliquot*, *Heidsieck*, *Irroy*, *Mott*, *Mumm*, *Perrier Jouët*, *Pommery-Greno*, and *Roederer*. Large quantities of sparkling wine are produced in the Saumur, in the department of Maine-et-Loire. Sparkling *Saumur* is made from both black and white grapes—the black being the product of the Breton vine, the white that of the Pineau blanc. The wine is made much in the same way as champagne, except that, as a rule, the finished product is a mixture of two successive vintages.

The wines of *Burgundy* (both red and white) are produced in the departments of Côte-d'Or, Yonne, and Saône-et-Loire. The principal red wines are *Mâcon*, *Beaune*, *Le Corton*, *Romanée Conti*, *Chambertin* and *Clos Vougeot*. *Hermitage*, when it can be obtained genuine, is a rich wine with purple colour, produced in the department of Drôme. The white wine of Yonne is known as *Chablis*, and is frequently, though incorrectly, described as 'White Burgundy.'

Spain. *Sherry*, the best known of Spanish white wines, is mainly produced in Andalusia, and derives its name from Jerez or Xeres de la Frontera, the chief centre of the trade, and where most of the wine is produced from must or fruit purchased from the growers. Sherries are essentially 'blended' wines, and are divided as regards type or quality into three classes: *Finos*, *Rayas*, and *Cortados*. The *Finos* are 'clean' and 'dry' in character, the *Rayas* being fuller in 'body,' whilst the *Cortados* partake of the characteristics of the other two types. These wines are exported, however, under various other names, as *Amontillado*, *Manilla*, *Montilla Solero*, &c. Sherries are almost invariably fortified and plastered, and the commoner kinds sulphured in addition, for the British market.

The sweet red wine known as '*tent*,' which is used for ecclesiastical purposes, is mainly obtained from the Rota district. This and the somewhat similar wines from the Tarragona, Valencia, and Alicante districts were formerly sold under the name of 'Tarragona Port,' or 'Spanish Port.' As the result of recent legislation, such descriptions are now illegal, the use of the term 'port' being applicable only to wines the produce of Portugal (*vide infra*).

Portugal. Port is mainly the produce of the rugged and mountainous district of the Alto Douro in the north-east of Portugal. The vintage usually begins at the end of September. The grapes, from which the stalks are removed, are emptied into stone tanks holding from seven to thirty pipes, and are pressed, first by treading and then by means of a beam or screw press. After from 48 to 60 hours' treading the must is left to ferment, drawn off into vats, and mixed with a sufficient quantity of alcohol to prevent acetous fermentation. After the lees are deposited the wine is again racked and mixed with more alcohol, which is usually obtained by distilling wine. If necessary, the wine is sweetened with 'jericopa,' or sweet must preserved with brandy. In the spring it is sent down to Oporto, where it is stored previous to shipment. 'Vintage wines' are those of the same origin, year, and quality, and are kept separately. The other principal types of port are 'Ruby' and 'Tawny.' These are usually blends, the former being intermediate in character between 'Vintage' and 'Tawny' ports. The latter is matured in wood, thus losing much of its deep red colour. Nearly half the wine exported from Oporto is sent to the United Kingdom.

Port first appeared in England at about the end of the seventeenth century, and its consumption in this country gradually increased up to the middle of the eighteenth century, since when it has gradually declined. The disfavour into which port has fallen may be partly due to the manufacture of numerous brands of inferior wines of port character, which may or may not be distinguished by qualifying names, as 'Hamburg Port,' &c.

As the result of representations by the Portuguese Government, definitions of 'Port' and 'Madeira' have been embodied in recent Acts of Parliament. Thus, in Sect. 1 of the Anglo-Portuguese Commercial Treaty Act, 1914, it is laid down: 'The description "Port" or "Madeira" applied to any wine or other liquor, other than

wine the produce of Portugal and the Island of Madeira respectively, shall be deemed to be a false trade description within the meaning of the M. M. Act, 1887.' Still later, in the Anglo-Portuguese Commercial Treaty Act, 1916 (Sect. 1) it is provided that, 'The description "Port" applied to wine the produce of Portugal imported into the United Kingdom after the passing of this Act shall be deemed a false trade description within the meaning of the M. M. Act, 1887, if the wine on importation into the United Kingdom was not accompanied by a certificate issued by the competent Portuguese authorities to the effect that it was a wine to which by the law of Portugal the term "Port" may be applied.' These enactments apply also to British 'made' wines.

The South of Portugal (Torres Vedras and Collares) produces a considerable quantity of a rough kind of claret, and also a white wine known in England as *Bucellas Hook*, which is obtained from the Riesling grape.

Italy. It is only within recent years that Italian wines have found much favour in this country, as they were formerly too sweet for the British market and deficient in keeping qualities. These defects have been largely removed by the adoption of more scientific methods of manufacture resulting in an increased popularity. Northern Italy produces *Barolo*, a red, and *Asti*, a white wine, together with a certain amount of sparkling wine. *Montepulciano* and *Chianti* are made in Central Italy; whilst the Neapolitan district yields *Lacryma Christi* and a variety of Malvoisie and good class Muscat wines. The island of Capri produces a good wine of *chablis* character.

Sicily. The chief Sicilian wine is *Marsala* (a white wine of light amber or brown colour, somewhat resembling sherry), obtained from a mixture of selected and thoroughly ripe grapes of the Madeira variety. It is carefully manufactured and is very uniform in quality, although, as a rule, somewhat heavily fortified, but not plastered.

Austro-Hungary. Both white and red wines are made, but those of German Austria are consumed for the most part locally. The best known are from *Vöslau* and *Gumpolds-Kirchen*, and the Tyrol. The most famous of Hungarian wines is the Sweet Tokay or *Essencia*, which is made from the first runnings of the ripe grapes obtained without pressure. Only a small portion is so obtained, and it rarely, if ever, appears in the market. Other varieties of Tokay are known as *Ausbruch* and *Mastas*. *Carlowitz* resembles port in character, and is produced on the banks of the Danube, about 40 miles to the north-west of Belgrade.

The greater portion of the wine produced in Bohemia (now incorporated in Czechoslovakia) is obtained from the province of *Melnik*, chiefly from the blue Burgundy grape, originally procured from France.

Excellent red wines, resembling Burgundy, are now made in Dalmatia. The most esteemed varieties are *Moscato Rosa*, *Maraschino*, and *Malvasia*.

Germany. The chief wine-producing districts of Germany are *Baden*, *Bavaria*, *Hesse*, the *Rheinland*, and *Württemberg*. The celebrated *Steinberg*, *Johannisberg*, *Riesling*, &c.

Gräfenberg, and *Zaunenthal* wines are produced in the neighbourhood of the Rhine, not far from Mainz, which is the centre of the hock trade. The vineyards of Hesse yield *Liebfraumilch*, *Nierstein*, and *Scharlachberg*; *Hochheimer* is obtained from the Maingau. The chief Rhine wine is the Riesling, which is said to be indigenous, and which has been transplanted and successfully cultivated in many other parts of the world as South Africa, Australia, and the United States

of America. The *Moselle* district also produces excellent wines of characteristic but rather weak flavour, which is often artificially enhanced by the addition of tincture of elder flowers.

The chief product is a white wine. A certain amount of red wine is obtained, notably *Assmannshausen*, from Riesling and mixed grapes. The results of analyses by König of wines from the principal European countries are shown in the following table.

ANALYSES OF EUROPEAN WINES (König).

	Number of analyses	Specific gravity	Alcohol by weight	Extract	Total acid as tartaric	Free tar- taric acid	Cream of tartar	Volatile acid as acetic	Sugar	Glycerol	Nitrogen	Ash

The Atlantic Isles. Grand Canary and Tenerife produce a small quantity of wine, but since the production of cochineal has fallen off on account of the preference for coal-tar colouring matters, vine culture is increasing, and wines of the Madeira type are being made in larger quantity.

Madeira. The best-known varieties of Madeira wine are *Malmsey*, and *Sercial*, the former being a sweet, and the latter a dry wine. It is a white wine, and its characteristic flavour is probably due to the practice of exposing the young grapes to a prolonged process of partial drying by artificial heat, and of heating the wine shortly after its manufacture to a temperature varying from 25° to 45°. Formerly the same condition was obtained by sending the wine a voyage to the East or West Indies and back. Very little red wine is made in Madeira (*vide supra*, under 'Port').

A small quantity of wine is made in the Azores, particularly on Pico, but it is of very indifferent quality, and is mainly exported as low-class sherry.

Cape of Good Hope. Comparatively little wine is now sent to this country from South Africa, although a century ago the importation of Cape wine into the United Kingdom exceeded that from France. The decline was due to vine diseases and insect pests, to faulty manufacture, and to fiscal changes. The best-known wines are *Veldt Burgundy* and *Claret*, *Wyndberg Okavies*, *Schoonvriest Hermitage*, *Tafelberg Hock*, and the sweet pale-red *Constantia* produced

near Cape Town. A great increase in the importation of South African wines has occurred since the war, the quantity imported during the last five years immediately preceding the war being only 15,000 gallons, as compared with over 200,000 gallons imported during the corresponding period since the war (1919-23).

Australia. Of late years the amount of wine from Victoria, New South Wales, and South Australia imported into this country has increased enormously. The industry may be said to be still in its infancy, but the most scientific methods and appliances are adopted, and the produce of such vineyards as Albury, Great Western, Highercombe, and Tintara bids fair to rival the best European wines of similar type.

In Australia (as in the case also of South Africa and California) the practice obtains of naming the wines after the well-known European types they more or less resemble in character, as 'Burgundy,' 'Chablis,' 'Hock,' &c., or after the variety of vine originally imported from Europe, as *Riesling*, *Hermitage*, and *Cabernet*.

United States. The manufacture of wine has been firmly established in California. The produce was originally derived from the 'Mission' grape, supposed to have been imported from Mexico by Franciscan monks, but German, French, and Spanish varieties were introduced, and wines in some degree resembling those of these countries (and named after their original types) were made on a considerable scale. The vine has been also cultivated on a large scale in Ohio, and clarets and champagnes have been

WINE.

made in the vicinity of Cleveland and Sandusky. Other wine-producing States were New York, Missouri, Illinois, and Pennsylvania. Whilst the finer wines consumed in the United States were obtained from France and Germany, the importation of foreign wines steadily decreased in favour of the home product.

It is understood that at the present time (1926) the national prohibition law prevents the manufacture and sale of wines in the United States.

The following are analyses, by Bigelow (U.S. Dept. of Agric. Bur. of Chem. Bull. 59), of 525 samples of wines manufactured in California:—

Description	Specific gravity	Alcohol by volume p.c.	Grams per 100 c.c.

ANALYSIS OF WINE.

The chemical examination of wine is usually restricted to the determination of those constituents which enable an opinion to be formed concerning its purity or freedom from adulteration, but expert tasting is of great importance, and microscopical examination of the deposits obtained from wine may afford useful information. For methods based on the latest chemico-physical principles, the work of Baragiola may be consulted (Zeitsch. anal. Chem. 1914, 53, 100; Analyst, 1914, 127).

For the estimation of the *specific gravity* a determination should be made by the bottle or other form of pycnometer and given accurately to four decimal places. Carbonic acid should first be removed by vigorous agitation.

The *results* are usually given in grms. per 100 c.c. or per litre. Koenig (Zeitsch. anal. Chem. 28, 202), however, deprecates this practice, on the ground that for sweet wines, which are liable to differ widely in sp.gr., the results are no longer directly comparable.

The *alcohol* is best determined by the distillation method, the sp.gr. of the weighed distillate being taken and the proportion of alcohol found from tables. For more exact determinations, the volatile acids should be neutralised before distillation.

Detection of cider in wine.—F. Schaffer (Mitt. Lebensm. Unters. Hyg. 1923, 15; Ann Chim. anal. 1924, 6, 88) has devised a method for detecting cider in wine, based on the diminished reducing power of the wine. The following modified procedure is recommended: Forty c.c. of the wine are decolorised by boiling with 3 grms. of pure animal charcoal and filtered, and the filtrate is heated to boiling with excess of precipitated calcium carbonate. After further filtration the cooled liquid is treated, slowly and with shaking, with 8 c.c. of 10 p.c. barium acetate solution, and again filtered. Five c.c. of the neutral filtrate are mixed with 2 drops of 0.2N silver nitrate solution, and, after being made alkaline by addition of 1 c.c. of 0.1N sodium hydroxide solution, are placed in the dark, and the time elapsing before distinct reduction is apparent is noted; the test should be made in duplicate or even triplicate.

With cider the reduction becomes evident in a few minutes, and with wines containing a marked proportion of cider in 10 to 20 minutes; in some cases comparison of the suspected wine with the natural wine of known purity is advisable (Analyst, 1924, 49, 235). If 1 c.c. of concentrated sulphuric acid be mixed (keeping cool) with 5 c.c. of wine and set aside till next day, genuine wine should remain clear (von Fellenberg, Mitt. Lebensm. Hyg. 1925, 16, 55; J. Soc. Chem. Ind. 1925, 44, B. 936).

Determination of extract.—The various methods in use for determining extractive matter in wine differ considerably both in principle and in the details of manipulation. The direct method (by evaporation) does not give comparable results unless the sugar of sweet wines and the potassium sulphate in plastered wines are deducted, and not then unless the estimation is conducted under exactly similar conditions.

The French official method of prolonged heating on a water-bath gives low results, owing chiefly to loss of glycerol. The sugar and potassium sulphate are deducted, an allowance of 1 gm. of each per litre being made to cover the amount of these substances assumed to be naturally present in fully fermented wine. The result is known as the 'reduced extract.'

The most exact determination of extract is made by evaporation (at the ordinary temperature) over sulphuric acid *in vacuo*, but as this requires from 3 to 6 days (according to the temperature) it is unsuitable for ordinary commercial use.

By Njegovius' modification of this method, however, the time may be reduced to within the limits of a working day. The wine (5 c.c.) is absorbed by anhydrous sodium sulphate (5 grms.) in a tared bottle and dried in a desiccator under diminished pressure, not exceeding 15 mm.

The German official method is as follows:—

(a) For wines with an extract amounting to not more than 3 grms. per 100 c.c. (ascertained by the indirect method (c) given below): 50 c.c., measured at 15°, are evaporated to a syrupy consistency on the water-bath in a platinum basin of 85 mm. diameter, 20 mm. height, and 75 c.c. capacity, and the residue is dried for 2½ hours in the water oven.

(b) For wines containing from 3 to 4 grms. of extract per 100 c.c. an amount yielding from 1 to 1.5 gm. of residue is taken. For the necessity of using dishes of similar area and surface in order to obtain comparable results, v. Bouchon (Compt. rend. 103, 498).

(c) For sweet wines, or those containing over 4 grms. of extract per 100 c.c., the indirect method of determining the extract from the sp.gr. of the wine after removal of the alcohol is to be preferred (v. Tables in Windisch, Die chemische Untersuchung und Beurtheilung des Weines, 338; abstracted, J. Soc. Chem. Ind. 1899, 280).

The amount both of extract and of alcohol may be determined by Riegler's refractometer method (Zeitsch. anal. Chem. 1896, 27). One gm. of alcohol and of extract in 100 c.c. of wine are found to raise the refraction by 0.00068 and 0.00145 respectively above that of water. Then if a = the refraction of pure distilled water; $(a+b)$ = the refraction of the wine from which the alcohol has been removed made up to the original volume taken; and N = the refraction of the original wine; then the formula
$$\frac{N - (a + b)}{0.00068}$$

gives the weight of alcohol, and $\frac{b}{0.00145}$ that of the extract as grams per 100 c.c. of the wine.

In completely fermented wines the amount of extract is seldom less than 14 grms. per litre. Wines containing less than this amount after removal of the sugar may be suspected of dilution.

After separation of the non-volatile acids, the remaining extract in natural wine is seldom less than 11 grms. per litre, and after separation of the free acids, as a rule, not less than 10 grms. per litre. The mineral constituents are usually about 10 p.c. of the extract.

The free acid is determined by titration with standard potash or soda-solution, using litmus-paper as indicator, and calculating the result as tartaric acid ($C_4H_4O_6$). Carbonic acid should first be expelled, either by heating just below boiling-point (but rapidly so as to avoid loss of acetic acid), or by agitation and subsequent titration in the cold. Volatile acids are determined by distillation in steam, or, since this partially volatilises lactic acid (Windisch, Zeitsch. Nahr. Genussm. 1905, 9, 70), by the difference in the acidity of the wine before and after evaporation to a small bulk, and are expressed as acetic acid ($C_2H_4O_2$). The fixed acids are estimated by difference between the total and volatile acids, or by direct titration of the extract obtained by evaporation *in vacuo*, and are expressed as tartaric acid. In France the acidity is usually given in terms of sulphuric acid (H_2SO_4).

Old wines have an acid reaction, in consequence of the presence of a certain amount of free acid and potassium hydrogen tartrate. A wine not exhibiting this acid reaction tastes flat. For a long time it was believed that the free acid of wine is tartaric acid alone. Nessler's researches have, however, shown that this is not the case. Tartaric and malic acids often come together, and more frequently the free acid consists of malic acid entirely. Wines containing tartaric acid alone taste more tart than

those with only malic acid, or a mixture of malic and tartaric acids.

The presence of free tartaric acid in wine does not necessarily show an improper admixture of tartaric acid with the wine. According to Mach and Rolandi, the amount of free tartaric acid in the grape increases in proportion to the degree of unripeness, so that its absence from wine can only occur under certain conditions of ripeness of the grapes employed. Although unripe grapes are frequently used in considerable quantity in wine-making, yet if the ripe grapes are in excess, the potash salts in them are more than sufficient to separate the free tartaric acid in the form of tartar, and this explains the fact that wine so made generally contains no free tartaric acid. A wine may be suspected of having been sophisticated if, with a small amount of free acid, an undue proportion of it is tartaric (J. Nessler and H. Wachter, Bied. Zentr. 1886; Chem. Soc. Abstr. 1880, 775).

The estimation of total tartaric acid, free tartaric acid, potassium bi-tartrate, and tartrates of the alkaline earths (lime and magnesia) is best made by the methods of Halenke and Möslinger, and of Barth (Zeitsch. anal. Chem. 1895, 279-290). These methods were officially adopted by a German Imperial Decree of 1896, an abstract of which is given in the J. Soc. Chem. Ind. 1898, 277. Certain modifications were introduced by Kulisch in 1901. Full details of these, as well as the French official methods, will be found in Post and Neumann's *Traité complet d'analyse chimique appliquée aux essais industriels*, 1910, tome ii. 661. The last three estimations are necessarily empirical, being founded on the assumption that all the bases present in the organic salts of the wine, or as carbonates in the ash, were originally combined with tartaric acid to form bi-tartrates.

A rapid and fairly accurate method of estimating tartaric acid and potassium in wine is that of Kling and Lassieur (Ann. Falsif. 1914, 7, 410; Analyst, 1915, 155). Mathieu (Ann. Falsif. 1919, 11, 80) recommends a method originally described by Pasteur in 1873. For details, see Analyst, 1919, 238. In a later communication he describes the process as follows: about 20 c.c. of the wine are shaken with 20 c.c. of amyl alcohol; the alcoholic layer is separated and shaken with an equal volume of water; the aqueous layer is drawn off, evaporated to dryness, the residue dissolved in 5 c.c. of water and the solution treated with 1 drop of calcium chloride solution (150 grams of crystallised $CaCl_2$ and 40 grams of NH_4Cl per litre) and 2 c.c. of 1-ammonium tartrate solution (20 grms. of the salt per 1 litre of dilute alcohol). A precipitate of calcium racemate forms immediately if the wine contains not less than 0.5 gm. of free tartaric acid per litre (Mathieu, Bull. Assoc. Chim. Sucr. 1921, 38, 352).

Numerous methods have been suggested for the estimation of malic and succinic acids, but they are too uncertain and inexact to be of much value for analytical purposes. The methods for estimating lactic and citric acids are more trustworthy, and the estimation of these is more important, since the former is a constant constituent of wines, and is often the cause of excessive acidity, whilst the latter is never present in genuine wines, except in small

but is sometimes added to sophisticated wines.

The best methods for estimating *lactic acid* are those of Kunz (Zeitsch. Nahr. Genussm. 1901, 4, 673) and Möslinger (*ibid.* 1901, 4, 1123). *Utric acid* may be estimated by Möslinger's method, weighing as lead citrate, as officially adopted by the U.S. Dept. of Agriculture (Bur. of Chem. Bull. 107, 81).

The determination of *glycerol* in wine has given rise to numerous processes, the best known of which are based upon either extraction by means of alcohol and ether or ethyl acetate or acetone and weighing, or oxidation to and estimation as oxalic acid.

Various methods have been proposed, as steam-distillation under reduced pressure (Bordas and Raczkowski, Compt. rend. 1897, 124, 240); or by conversion into triacetin (Böttger, Chem. Zeit. 1897, 659); or into isopropyl iodide and weighing as silver iodide (Zeisel and Fanto, Zeitsch. anal. Chem. 1903, 549).

The Zeisel-Fanto method always gives low results. Correct values, however, can be obtained when organic acids, such as acetic, propionic, succinic, or tartaric acid, which have a decomposing action on the polyglycerol formed, are added to the reaction mixture. Lowering the concentration of hydriodic acid has no influence on the result: 200 c.c. of wine after treatment with tannin and barium acetate in the usual way are concentrated to about 30 c.c., and diluted with water to 40 c.c. 10 c.c. of the filtrate are then diluted to 50 c.c. with acetic acid, and 5 c.c. of this solution employed for the determination (C. Marchi, Staz. sperim. agrar. ital. 1923, 56, 231; Chem. Zentr. 1923, 94, [iv.] 1011; J. Soc. Chem. Ind. 1924, 43, B. 110).

A method by Rothenfusser, claimed to be more rapid and less laborious and expensive than the official method described below, is given in Zeitsch. Nahr. Genussm. 1913, 26, 535.

The older methods, especially extraction with alcohol and ether, are generally preferred, since, although somewhat empirical, they yield results which are comparable with the enormous amount of similar data acquired by previous observers. It is essential, however, that the exact details of the given methods should be rigidly followed.

The method officially adopted in Germany is as follows, (a) being adopted in the case of dry wines or those containing less than 2 grms. of sugar per 100 c.c.; and (b) for sweet wines containing more than this proportion of sugar.

(a) 100 c.c. of wine are evaporated down to 10 c.c. in a porcelain capsule on a water-bath. 1 gm. of quartz sand is added and milk of lime (40 p.c.) equivalent to 1½–2 grms. CaH_2O_2 for each gram of extract present, and evaporation continued almost to dryness. The residue is then repeatedly boiled with small quantities of 96 p.c. alcohol, the various extracts being decanted into a 100 c.c. flask, made up to bulk at 15°, filtered, and 90 c.c. of the filtrate evaporated in a porcelain capsule on the water-bath (without boiling). The residue is washed into a stoppered graduated cylinder with small quantities of absolute alcohol until 15 c.c. are collected, then shaken up with three successive

portions of ether (7·5 c.c. each time), and, when clear, the whole (including the rinsings of the cylinder with alcohol-ether, 2:3) evaporated on the water-bath to a syrup, but without boiling. The residue is dried for 1 hour at 100°, cooled, and weighed. The weight in grams, multiplied by 1·111, gives the number of grams of glycerol in 100 c.c. of the wine.

(b) 50 c.c. of wine are heated on the water-bath in a large flask, 1 gm. of quartz sand added, also milk of lime until the dark colour at first produced disappears, and an alkaline odour becomes evident. After cooling, 100 c.c. of 96 p.c. alcohol are added, the precipitate filtered off and washed with alcohol. The filtrate is evaporated and treated as in (a). The factor 2·222 is necessary in this case to obtain the number of grams of glycerol in 100 c.c. of the wine.

A method of estimating glycerol in wine is based upon its conversion into acetaldehyde by means of boric acid, the distilled aldehyde being determined by standard silver nitrate solution (Heiduschka and Englert, Zeitsch. anal. Chem. 1921, 60, 161).

For a process involving the use of acetone as solvent, see Beis, Bull. Soc. Chem. 1912, 11, [iv.] 618; Analyst, 1912, 37, 351; Bertinchand, *ibid.* 1913, 38, 368.

The sugar in wine is a variable mixture of dextrose and levulose, and occasionally sucrose. The usual method of examination consists in estimating the total quantity of sugar by titration with copper solution, then ascertaining by the optical method the proportions of the two glucoses and estimating the sucrose after inversion with hydrochloric acid.

Valuable information as to the nature and proportions of the sugars (both natural and added), as well as of other optically active substances introduced for the purpose of sophistication, may be obtained by the use of the polarimeter. Pure wine which still contains unfermented sugars turns the plane of polarisation to the left, whilst perfectly fermented wine either does not polarise at all, or only very slightly to the right. Wines sweetened with commercial glucose may contain considerable proportions of dextrorotatory non-fermentable substances.

It is essential to remove alcohol and colouring matters, and Neesler and Barth show that it is a matter of considerable importance also to remove the tartaric acid present in the wine, and they add, before precipitating with alcohol, a few drops of a strong solution of potassium acetate, thus separating the tartaric acid as potassium hydrogen tartrate.

The wine is carefully neutralised, and the alcohol eliminated by evaporation, the residue filtered, if necessary, and made up to original bulk, decolorised with lead acetate, the excess of lead removed with sodium carbonate or sulphate, and the polarimeter reading corrected for the increased volume due to these additions. The use of bone black should be avoided if possible, and complete decolorisation is not necessary if the liquid is clear. Turbidity can be removed by the addition of alumina cream.

A complete scheme, based upon the German official methods (Veröffentl. d. Kaiserl. Gesundheitsamts, 1896, 20, 557) is given in Allen's

Commercial Organic Analysis, 1924, vol. i. 230. The results are obtained from observations in a 900 mm. tube, and expressed in terms of the sugar scale of the Schmidt and Haensch half-shadow saccharimeter.

For the estimation of sugar by Barreswil's (Fehling's) solution, the tannin must first be removed by lead acetate, the excess of lead being precipitated by sodium carbonate or sulphate. Ordinary fully fermented wine usually contains under 0.1 p.c. sugar, and may be decolorised by a small quantity of animal charcoal. Either the gravimetric method (weighing the precipitated copper as CuO) or the volumetric (using as indicator either potassium ferrocyanide or ferrous thiocyanate as recommended by Ling (Analyst, 1905, 182; 1908, 160)) may be used.

Sucrose may be determined by difference between the directly reducing sugars formed as just described, and the total reducing sugar after inversion with hydrochloric acid on the water-bath, deducting one-twentieth of the difference (invert sugar) thus found to obtain its equivalent as sucrose; or the Clerget polariscopic method may be employed, using Herzfeld's modification of the Clerget formula (*v. art. SUGAR*).

The shoots and leaves of the vine, as well as unripe grapes, contain both sucrose and dextrose. The quantity of sucrose in the grapes gradually diminishes to zero as the grapes ripen, whilst the quantity of dextrose reaches a maximum at the period of ripeness. Sucrose, when added to wine, is gradually converted into dextrose, an addition of 5 p.c. being no longer traceable after five months, and 8.5 p.c. being completely transformed in six months. Boiled grape juice contains a substance which, after hydrolysis with acids, reduces Fehling's solution, and might thus be taken for sucrose. No rotation of polarised light can, however, be detected, and the substance is probably glucosan. In the case of wines, therefore, which have been sweetened with boiled grape juice or coloured with caramel, it is unsafe to conclude, from the reduction of Fehling's solution, that sucrose is present unless its presence is also indicated by examination in the polarimeter (O. Klein, Zeitsch. angew. Chem. 1924, 37, 111; J. Soc. Chem. Ind. 1924, 43, B. 486).

Gum arabic and dextrin, which are sometimes used for sophisticating wines, may be detected by adding to a little of the wine about twice its bulk of the strongest alcohol. If a decided flocculent and viscous precipitate be formed, the gum is obtained by evaporating 100 c.c. of the wine to about 5 c.c., and precipitating by the gradual addition of 90 p.c. alcohol. The precipitate is filtered off, dissolved in about 30 c.c. of water, 1 c.c. of strong hydrochloric acid added, and the liquid heated in a flask provided with a long glass tube as a reflux condenser for 3 hours on a bath of boiling water. The sugar thus produced is then estimated in the usual manner by Fehling's solution.

Tannin.—There is no very exact method for the estimation of tannin in wine. That of Neubauer-Löwenthal is recommended, and is described, with modifications, by Fresenius and Borgmann in 'Analyse des Weines,' 1922, p. 74.

Mineral matter is found by cautious incineration of the residue from the evaporation of 50 c.c. of the wine, taking the usual precautions for

separation of carbon from the alkaline salts. Rapid weighing is essential owing to the hygroscopic nature of potassium carbonate.

The determination of the ash (and of several other constituents) of wine containing much sugar is often facilitated and made more exact by eliminating the alcohol and removing the sugar by fermentation.

Wine containing less than 1.3 mineral matter per litre may be suspected unless it can be shown that natural wine from the same district and of the same vintage actually contains so small an amount of inorganic matter. The ratio of mineral matter to extract is, as a rule, about 1 to 10.

Estimation of chlorine in wine.—It is well known to wine falsifiers that chemists lay much stress on the proportion of mineral matters contained in wine, and therefore they frequently add sodium chloride to artificial or adulterated wines in order to increase the extract and to bring the total amount of ash up to the normal quantity. It is also said to hasten clarification and to have a preservative effect. Owing to the volatility of sodium and calcium chlorides on incineration, chlorine is best determined in the wine itself and not in the ash, but the ordinary method of titration is inapplicable owing to the solubility of silver chromate in the free acid of the wine. The chlorine is either precipitated and weighed as silver chloride, or the method of Nessler and Barth may be employed as follows:—50 c.c. of the decolorised wine are acidified with nitric acid, an excess of standard silver solution is added, and then standard thiocyanate solution is run in until a drop of the liquid when mixed on a plate with ferric sulphate solution just shows a pink coloration.

Wines containing more than 0.05 p.c. sodium chloride may as a rule be suspected. Exceptions may occur in the case of wines which have been produced in the neighbourhood of the sea-shore.

Alkaline earths in wine.—The ash of wine always contains calcium and magnesium salts. The amount of calcium (3.11.4 mg. in 100 c.c. of wine) is greatest in young wines and gradually diminishes with age, probably in consequence of the separation of neutral calcium tartrate. The amount of magnesium, on the other hand, remains almost constant and is always in excess of the calcium. The largest amount of magnesium found by Kayser was 24 mg. in 100 c.c. of Malaga wine. The phosphoric acid and magnesia show a constant proportion of 10:6, corresponding with the formula MgHPO_4 , (Kayser, Chem. Zentr. 1881, 394; Chem. Soc. Abstr. 1882, 121).

Barium and strontium salts are sometimes added, to remove sulphuric acid, in the process of 'deplastering' wines, and are best detected in the ash, which should be taken up with dilute hydrochloric acid, filtered, and the filtrate evaporated to dryness. The dry residue is then examined by the spectroscope. If barium or strontium is present they are determined quantitatively in the usual manner.

Sulphuric acid is precipitated directly with barium chloride in wine acidified with hydrochloric acid, and determined in the ordinary manner.

A normal wine contains not more than 1.3 gm. K_2SO_4 per litre, and when the amount

exceeds 2 grms., the wine may be regarded as plastered or sulphured.

The determination of phosphoric acid is to be effected in the ash by the molybdc method. (For details, see J. Soc. Chem. Ind. 1898, 280.)

The total phosphoric acid may be determined directly (without incinerating the residue) by Grete's volumetric method (Ber. 1909, 42, 3108).

The addition of dicalcium phosphate is sometimes made instead of 'plaster,' and is said to have certain advantages over the use of gypsum.

Nitric acid is sought for by carefully adding a few c.c. of the wine to a solution of diphenylamine in (pure) concentrated sulphuric acid, without mixing, and avoiding rise in temperature. An intense blue colour at the junction of the liquids indicates the presence of nitric acid.

Fresenius (Zeitsch. anal. Chem. 28, 67) finds that in wines containing much sugar a loss of phosphoric acid takes place during the incineration of the residue. A higher result is obtained when the residue is deslagged with alkaline carbonate and nitrate. Destruction of the sugar by fermentation by addition of a very small quantity of yeast leads to the same result.

The assumption that the better kinds of wine always contain more phosphoric acid than the poorer ones is unfounded. At the same time the amount of the phosphoric acid can, in many cases, serve as a valuable means of ascertaining the character of a wine, especially of wines used for medical purposes, or of those of a particular district in which the amount of phosphoric acid varies between definite limits.

Examination for colouring matters.—The principal substances used in red wines are vegetable colouring matters, coal-tar colours (especially fuchsines), and cochineal. White wines are frequently coloured with caramel or coal-tar colours used as substitutes.

According to Jean and Frabot (Ann. Chim. anal. 1907, 12, 52), wines artificially coloured may be distinguished from natural wines by the following test. The wine (50 c.c.) is heated on a water-bath with a little formalin (1 c.c.) and hydrochloric acid (4 c.c.), and when a precipitate is formed the liquid is made alkaline with ammonia and the excess expelled by further heating. The liquid, on cooling and filtration, yields a colourless filtrate in the case of genuine wines, whilst artificially coloured wines yield a coloured filtrate.

(a) *Vegetable colours.*—These are derived chiefly from bilberries, black cherries, elderberries, hollyhock or rose-mallow, poke-berries (*Physalacca*), indigo and 'lichens (archil, &c.), alkanet root, Campeachy, Pernambuco, and other dye-woods.

The wine is mixed with an excess of lead acetate and filtered. The colour of the precipitate in a genuine red wine may be greyish-blue, bluish-grey, ash colour, or greenish. If a precipitate is obtained not greatly differing from these colours, the search for other vegetable pigments can give no certain result. The colouring matter of bilberries gives a blue precipitate; mallow and elderberries a green. The colour of *Physalacca berries* differs from that of red wine by giving a red-violet lead precipitate (see also Lens, Zeitsch. anal. Chem. 1895, 635).

Alkanna-red, which, with Dupré's test (a.

ing), behaves very like the natural colouring matter of wine, is very easily taken up from its solutions by amyl alcohol. On adding to the amyl alcohol a solution of a few drops of olive oil or oil of almonds and evaporating off the alcohol, the oily residue (after washing with water) has a fine red colour, which, on saponification becomes a rich blue, or if the alkanna used was old, a green (Herz, Zeitsch. anal. Chem. 23, 637; Chem. Soc. Abstr. 1890, 311).

Beetroot juice is used in colouring wines for the purpose of concealing the presence of magenta. The absorption-bands of magenta are hidden by those of beetroot, but if a few drops of copper sulphate solution are added to the wine, the beetroot bands gradually vanish and the magenta spectrum becomes visible.

The fresh colouring matters of bilberries and wines are similar but not identical, and, according to H. W. Vogel (Ber. 21, 1746), they are readily distinguished by their absorption spectra after careful neutralisation with ammonia, or, better still, when they are treated with a trace of alum before addition of ammonia. Care must be taken that the wine is not too concentrated or the ammonia in too great excess.

Detection of logwood in wine.—When a solution of logwood is treated with manganese dioxide it becomes brown, and this brown liquid, by the action of zinc and hydrochloric acid, gives a colourless solution of hæmatoxylin. This may be detected by the ordinary reagents for that substance, alkalis and their carbonates giving a blue-violet coloration, calcium hydroxide a red-violet, stannous chloride or ammonium molybdate, in a solution slightly acid with nitric acid, a violet coloration. Advantage has been taken of this reaction for the detection of logwood in wines. 20 c.c. of the wine is agitated with 2 grms. finely powdered manganese dioxide, filtered, and the brown liquid treated with zinc and hydrochloric acid, which reduces the oxidised logwood colouring matter to hæmatoxylin. The solution is then divided into several portions, and tested with the reagents given above. Pizzi has examined wines to which other red colouring matters have been added, and although these yield brown solutions with manganese dioxide, the reduced solution does not give the hæmatoxylin reactions. Brazilwood is the only one which has any analogy to logwood, but here also there are differences (Chem. Soc. Abstr. 1881, 761).

Spaeth (Zeitsch. Nahr. Genussm. 1899, ii. 635; Analyst, 1900, 11) gives a table of reactions which may be found useful for the detection of the most commonly used vegetable colours.

(b) *Coal-tar colours.*—In most cases the presence of a coal-tar colour in wine may be recognised by the following methods:—

a. By shaking the filtrate, after precipitating with basic lead acetate, with amyl alcohol, or (i.) the wine itself, also (ii.) a portion of the wine acidified with sulphuric acid, and (iii.) a portion made alkaline with ammonia. In the latter case, excess of ammonia should be avoided, as, if more than 3 p.c., the amyl alcohol may remain colourless, although the wine contains a coal-tar colour. The amyl alcohol extract in (i.) and (ii.) may contain natural colouring matter of the wine, but if the colour remain unchanged by ammonia, the presence of a coal-tar colour may

be inferred. The amyl alcohol extract from (d.) should be shaken up with water and the aqueous solution tested with ammonia or by the wool test.

b. By the wool test, using alum and sodium acetate as a mordant, and adding about 1 p.c. of potassium sulphate in solution.

c. By Cazeneuve's oxide test (*Vierteljahrsschrift für Chemie der Nahrungsmittel*, 1896, 80; *Compt. rend.* 102, 52).

The oxides employed are yellow mercuric oxide in the proportion of 0.2 grm. per 10 c.c. of wine; lead hydroxide, containing 50 p.c. of water, in the proportion of 2 grms. per 10 c.c.; and gelatinous ferric hydroxide, containing 90 p.c. of water, in the proportion of 10 grms. per 10 c.c.

Mercuric oxide completely absorbs the natural colouring matter, cochineal and foreign vegetable colours, erythrosin, eosin J, methylene blue, Coupler's blue, and diphenylamine blue. It partially absorbs orange I., safranine, chrysoidine, chrysone, methyleosin, yellow II., red NN, red I., and Ponceau RR. It does not absorb the sulpho-conjugated derivative of rosaniline, Bordeaux red B, Ponceau R, Ponceau B, orange R, orange RRR, orange II., orange RR, tropaeoline M, tropaeoline II., yellow L, solid yellow, dinitronaphthol yellow, U. S. yellow.

Lead hydroxide completely absorbs the natural colouring matter, cochineal and foreign vegetable colours, methylene blue, Coupler's blue, diphenylamine blue, and erythrosin. It differs from mercuric oxide in not absorbing the rosanilines, and also in absorbing the sulpho-conjugated derivative of rosaniline, Bordeaux red B, the purple red, and soluble red of rocelline.

Ferric hydroxide does not absorb erythrosin, the sulpho-conjugated derivative of rosaniline, Bordeaux red B, purple red, soluble red, and solid yellow. It absorbs the natural colouring matter and foreign vegetable colours, cochineal, and all the derivatives of rosaniline, except the sulpho-conjugated derivative.

Zinc hydroxides and stannous hydroxide behave similarly. The latter retains the natural colouring matter, but does not absorb cochineal or orcein. After the wine has been treated with the hydroxides, the colouring matters must be distinguished by special tests. If the wine is treated with magnesia and hot amyl alcohol, a number of blues which are precipitated by the above-mentioned hydroxides can be isolated and distinguished.

d. Shaking the wine with ether before and after supersaturation with ammonia.

Five to 6 c.c. of the wine to be tested are poured into a glass test-tube of about 20 c.c. capacity, and then three-quarters of its bulk of ether is added. After a few minutes the ether rises to the surface of the wine. If the ether be coloured yellow, and assumes, on addition of some drops of ammonia, a deep-red tint, Campeachy-wood has been used to colour the wine. If the ether becomes red and violet, and remains so even on addition of a large quantity of ammonia, the wine contains colouring matter derived from some of the lichens.

If the red-coloured ether loses its tint on mixing with ammonia, without passing into violet, then only the natural colouring matter of the wine is present. If the red-coloured

ether loses its red tint with ammonia, without imparting any colour to the latter, then fuchsin has been added to the wine. When the ether rises uncoloured, a fresh sample of the wine to be tested is taken, twice its volume of water is poured into it, and half its volume of ammonia added. If the wine now assumes a brownish-red colour, it contains cochineal; if, however, it turns green, then it can be assumed that none of the substances mentioned is present.

e. The formation of isonitriles when aniline derivatives are warmed with potash and chloroform serves for the direct determination in wine of even minute traces of many of the aniline colours. The evolution of the isonitrile is accelerated by adding excess of strong sulphuric acid.

According to A. Dupré, fraudulent colouring matters added to red wines may be detected by dialysis, which is best accomplished by placing in the wine a cube of jelly about $\frac{1}{2}$ -inch side. These cubes are made by dissolving 10 grms. of gelatin in 100 c.c. of warm water, and pouring the solution into a flat dish or mould; from the plate thus obtained the cubes are cut. After 24-48 hours the cube, on examination by transmitted light, will be found to be coloured more or less deeply by any colouring matter present, excepting the natural colouring matter, which penetrates only to a depth of $\frac{1}{8}$ -inch at the most. The colouring matter of alkanet root also penetrates but slowly, whereas rosaniline, cochineal, logwood, brazilwood, indigo, litmus, red cabbage, beet-root, *Malva sylvestris*, and *Althea officinalis* penetrate rapidly into jelly (*Chem. Soc. Trans.* 1880, 572).

The nature of the colouring matter may be determined either by the colour of the jelly or spectroscopically, or by the action of dilute ammonia, which turns cochineal purple, logwood brown, red cabbage dark green, and decolorises rosaniline (r. SPECTRUM ANALYSIS).

Bordeaux verdissant or 'colorant introuvable' is a mixture of acid fuchsin with methylene blue and diphenylamine orange, the two latter colours being used to produce a green which becomes visible on decolorising the Bordeaux red with ammonia, thus simulating the effect of ammonia on natural red wine. The diphenylamine orange can be extracted with amyl alcohol, the acid fuchsin detected by Girard's mercuric acetate test, and the methylene blue by dyeing cotton fibre.

A substance known as *Tintura por los vinos* is said to have been largely used for colouring certain Spanish wines. It is alleged to contain Biebrich red, sodium sulphate, and arsenious oxide. The presence of arsenic, if a fact, is of special importance.

The methods employed in the Paris Municipal Laboratory for the investigation of the colouring matters in wine will be found in Girard and Dupré's *Analyse des matières alimentaires*.

Removal of added colouring matter from wine.—So much artificially-coloured wine is confiscated in certain districts in Italy that the authorities are considering the advisability, in the interests of economy, of merely removing the added colouring matter from the wine instead of denaturing the latter before returning it to the owners. For effecting this removal the following methods may be employed: (1) Addition

to the wine of must, thus causing a fresh alcoholic fermentation; (2) addition of young wine, the proteins of which may form insoluble compounds with the colouring matter; (3) clarification by means of egg albumin, fish glue gelatin, &c.; (4) keeping the wine for some time, with repeated transference. The colouring matter most commonly used is 'vinolin,' a mixture of Bordeaux B, Bordeaux R, and Ponceau RRR, which may be eliminated by re-fermentation of the wine in presence of vinasse (F. Scurti, *Annali Chim. Appl.* 1923, 13, 194-200; *J. Soc. Chem. Ind.* 1923, 42, 993 A).

Detection and estimation of *preservatives* most commonly used in wine. *Abrastol* or *asaprol* (calcium α -monosulphonate of β -naphthol) is a white or slightly reddish scaly powder readily soluble in water and alcohol, and decomposing at 50°. It is extracted from alkaline solution by amyl alcohol, the extract evaporated to dryness, and the residue tested by Sinibaldi's method (*Mon. Sci.* 1893, [iv.] 7, 842; U.S. Dept. of Agric. Bur. of Chem. Bul. 59, 91).

Boric acid (according to Baumert, Ber. 21, 3290) is naturally present in many wines as well as in the leaves and tendrils of the grape-vine. It is detected in the ash by extracting with a large excess of strong hydrochloric acid, and testing with turmeric paper. For its quantitative estimation, see Windisch, *Die Chemische Untersuchung und Beurtheilung des Weines*, 235.

Fluorides are strongly antiseptic and are usually employed in very small quantity in the form of the ammonium or sodium salts which are soluble in water. The fluoride is precipitated as calcium fluoride from alkaline solution by means of calcium chloride, and the precipitate, after filtering, washing, drying, and heating in a platinum crucible, is tested by means of the 'etching' test. A blank experiment should be made with the reagents employed. For *fluoborates* and *fluosilicates* the ash containing the calcium salts is extracted with dilute acetic acid and filtered. The filtrate contains the boric acid which, if present, is detected as above. The calcium fluoride and silicate remain in the insoluble portion, and can be detected by the usual methods (v. Bull. 59, 63, U.S. Dept. of Agric. Bur. of Chem.).

For detecting *saccharin* (which is used as a preservative as well as a sweetening agent), the wine (about 100 c.c.) is shaken up with a mixture in equal parts of ether and light petroleum, and the extract, after evaporating off the solvent, is fused with sodium hydroxide and tested by means of ferric chloride for salicylic acid. It is assumed, of course, that the absence of salicylic acid in the original wine has been proved and the presence of saccharin indicated by the sweet taste of the residue from the ether extraction.

The estimation of the saccharin may be made by acidifying (if necessary) with phosphoric acid, extracting with ether as above, and fusing the evaporated residue with a mixture of sodium carbonate and nitre, precipitating the resulting sulphate with barium chloride and calculating the saccharin from the weight of barium sulphate obtained ($\text{BaSO}_4 \times 0.785 = \text{saccharin}$).

Saccharin may also be estimated by hydrolysing the residue from the ether extract with hydrochloric acid, and estimating the ammonia

thus formed by distillation into standard acid (Proctor, *Chem. Soc. Trans.* 1905, 242).

Salicylic acid is best sought for by agitating the wine with carbon disulphide or a mixture of equal volumes of ether and light petroleum (taking care to avoid an emulsion), evaporating down and testing the residue with ferric chloride. If much more than 100 c.c. are used, a faint colour may be occasioned by other substances giving a similar reaction and present as normal constituents of the wine.

An approximate estimation of the quantity of salicylic acid may be made colorimetrically, by comparing the colour given by an alcoholic solution of the residue after ether extraction with that yielded by standard alcoholic solutions of salicylic acid of known strength, using, if possible, a liquid similar to that under investigation.

Sulphurous acid and sulphites.—Wine will absorb as much as 0.36 gm. of sulphurous acid per litre when it is shaken in a barrel in which sulphur has been burnt, and if the treatment is repeated the sulphurous acid may reach 0.5 gm. per litre. Sulphur is burnt in the barrels to prevent the formation of mildew, and sulphites are sometimes used as a preservative. Much of the sulphurous acid is combined with aldehyde when it is considered to be much less objectionable than in the free state.

Sulphurous acid is determined by distilling a portion of the wine, to which phosphoric acid has been added, in a stream of carbon dioxide, receiving the distillate in solution of iodine, and determining the sulphuric acid thus formed. The details of the method are as follows (B. Haas, Ber. 15, 154): the wine, to which 5 grms. of syrupy phosphoric acid have been added, is distilled in a current of carbon dioxide, and the distillate is collected in a suitable apparatus (a bulb U-tube) containing 50 c.c. of iodine solution (containing 5 grms. pure iodine and 7.5 grms. potassium iodide per litre), thus oxidising the sulphurous acid. As soon as the distillate amounts to about half the original volume of the wine used, the contents of the U-tube are washed out, acidified with hydrochloric acid, precipitated with barium chloride, and the barium sulphate washed, dried, heated to redness, and weighed. This method gives very good results. The sulphurous acid may also be oxidised by means of hydrogen peroxide, using barium peroxide, and weighing as barium sulphate (Levi, *Ann. Fabrif.* 1913, 6, 5; *Analyst*, 1914, 87).

Opinions vary as to how much sulphurous acid a wine may contain. According to the medical faculty of the University of Vienna, not more than 8 mg. per litre should be allowed, whereas other authorities regard 80 mg. as not an excessive amount. In France and Switzerland the maximum limit is fixed at 200 mg. of SO₂ per litre, of which, in France, not more than 30 mg., and in Switzerland, not more than 20 mg. should be 'free' or uncombined.

Poisonous metallic substances in wine.—Traces of arsenic may be present owing to the use of impure coal-tar colours (acid fuchsine, &c.), and commercial glucose. Copper and mercury may be due to the compounds used as insecticides and fungicides, but are, no doubt, largely removed in an insoluble form during the process of fermentation.

mentation. Lead has been traced to the use of litharge to mask acidity and to lead shot used for cleaning bottles. Zinc is often present in appreciable quantities when the wine has been stored in vessels of unalloyed zinc. These metals may be detected and estimated by the usual methods.

Hydrocyanic acid may be present in wine to which potassium ferrocyanide has been added to remove the iron. For its detection and estimation, see Mach and Fischler (Zeitsch. Unters. Nahr. Genussm. 1924, 47, 329; Reichard, *ibid.* 1924, 47, 339; Zeitsch. angew. Chem. 1924, 37, 957).

Alum is occasionally present in the coal-tar colours employed, and is sometimes added to wine as a clarifying agent, and to impart astringency, particularly to wines which have been diluted. The alumina may be estimated as follows (Louvet, Chem. Zentr. 1881, 252): 200 c.c. of wine are evaporated to dryness, the residue incinerated, and the ash fused in a platinum crucible with 3 grms. sodium carbonate, whereby the lime, magnesia, and ferric oxide are converted into insoluble carbonates. The mass is dissolved in water, and the solution filtered. As the solution may contain sodium aluminate, it is acidified with hydrochloric acid, treated with a large excess of sodium carbonate, and the alumina collected on a tared filter. The insoluble portion of the fused mass, containing the chief portion of the alumina, is fused with a few grams of pure soda, and the fused product digested with water and the solution treated for alumina as above described. The precipitates are collected, thoroughly washed, dried, ignited, and weighed. If any considerable proportion of phosphate is present, the phosphoric acid should be estimated and deducted from the total weight, the difference being Al_2O_3 .

Adulteration of wine.—Of the various processes already described which, strictly speaking, might be considered as 'adulteration,' some, as fortifying with spirit, sweetening with sugar, glucose, or glycerol and 'plastering,' are defended as legitimate trade practices of long standing or are officially tolerated within certain limits. Others, as dilution with water, the addition of antiseptics, astringents, colouring matters, and mineral acids, and of potassium hydrogen tartrate and ceanothic ether to give the fictitious character of age, have, as a rule, no other object than that of fraud.

In addition, wine is mixed with the juice of fruit other than the grape, and spurious wines containing no grape-juice whatever are made to simulate well-known types, as port, sherry, claret, and burgundy. The fruit basis of these is usually apple juice (v. p. 480), the other principal ingredients employed being crushed raisins, alcohol, sugar, tartar, flavouring essences, and colouring matters derived generally from the juice of such fruits as bilberry, elderberry, black currant, etc.

For the detection of dilution with water, fortifying with spirit, the addition of acids, tartar, glycerol, sugar, and other forms of sophistication of wines, reliance is placed in France and Germany upon the ratios which the proportions of the principal constituents of the genuine wines of those countries bear to each other (e.g. in France, alcohol : extract (reduced) : and in Germany, alcohol : glycerol); and certain

maxima and minima are adopted for the constants of genuine wines; but it does not necessarily follow that these can be accepted as standards applicable to the wines made in other countries and by different methods of manufacture. Whenever possible the suspected wine should be compared with a similar wine from the same district and vintage and known to be genuine. A concise and clear résumé of these constants and ratios will be found in Allen's Commercial Organic Analysis, 1924, vol. i. 242-7; see also Thudichum and Dupré's Treatise on the Origin, Nature, and Varieties of Wine; Windisch's Die chemische Untersuchung und Beurtheilung des Weines; Villiers et Collin, Traité des alterations et falsifications des substances alimentaires; Leach's Food Inspection and Analysis; and Post and Neumann's Traité complet d'analyse chimique appliquée aux essais industriels. WINE GUM v. GUMS.

WINTER GREEN, OIL OF, v. OILS, ESSENTIAL, and SALICYLIC ACID

WITGATBOOM. The dried root of *Boscea Transvaalensis*, Pest., *B. rehmanni*; *Marua pedunculata*, Sim.; and *Capparis albiflora*, Burch. Used as a substitute for chicory in certain parts of South Africa. For the microscopic and analytical characters of the roots and their aqueous extracts, see McCrae and Klooh, Analyst, 1918, 373.

WITHANIA SOMNIFERA, a plant found in South Africa, on the west coast of India, and along the shores of the Mediterranean. The root contains an essential oil, a quantity of sugar yielding *d* phenyl-glucosazone (m.p. 210°); a black resin from which the following substances have been isolated: hentriacontane $C_{31}H_{64}$; a phytosterol $C_{27}H_{46}O$ (m.p. 135°-136°); palmitic, stearic, cerotic, oleic, and linolic acids; ipuranol $C_{22}H_{40}O_4(OH)_2$; a monohydric alcohol, *witkaniol*, $C_{22}H_{42}O_4(OH)$, decomposing at 305°, and having $[\alpha]_D +91.2^\circ$, and an amorphous alkaloidal principle, which, on treatment with alkalis, yielded a crystalline base, $C_{17}H_{21}N_2$ (m.p. 116°).

The leaves and stems contain, in addition, a monohydric alcohol, *somnirol*, $C_{22}H_{44}O_4(OH)$, decomposing at 205°, and having $[\alpha]_D +34.8^\circ$; a dihydric alcohol, *somnitol*, $C_{22}H_{44}O_4(OH)_2$, decomposing at about 250°, and having $[\alpha]_D +21.2^\circ$; and an acidic hydrolytic product, *witkianic acid*, $C_{18}H_{32}O_4.CO_2H$ (m.p. 226°), the methyl ester of which decomposed at 255° (Power and Salway, Chem. Soc. Trans. 1911, 98, 490). These authors were unable to confirm the sedative and hypnotic properties attributed to this plant.

WITHERITE. Native barium carbonate ($BaCO_3$) crystallising in the orthorhombic system and isomorphous with aragonite and cerussite. The crystals are, however, invariably twinned, giving rise to pseudo-hexagonal forms; these may be either lenticular or pyramidal in habit, and in the latter case the six-sided pyramids present a certain degree of resemblance to crystals of quartz. Globular aggregates and compact fibrous masses also occur. The colour is white or grey; sp. gr. 4.3; H. 3½. The mineral occurs in some abundance in the lead-bearing veins traversing limestones, &c., at several places in the north of England and

on the borders of Shropshire and Montgomeryshire. It has been formed, in some instances at least, by the action of carbonated waters on barytes (L. J. Spencer, Min. Mag. 1910, 15, 310); and it is itself sometimes altered to barytes, as shown by the pseudomorphs of barytes after witherite. The best known locality, which has yielded many finely crystallized specimens, is the Fallowfield mine near Hexham; whilst the largest quantity (about 8000 tons per annum) is produced by the Settling-stones mine also in Northumberland. The mineral is also known from a few foreign localities, but only in small amounts.

Witherite is used in the manufacture of plate glass and porcelain, and for the preparation of barium dioxide (used in the manufacture of hydrogen peroxide), barium hydroxide (for refining beet-sugar), and barium salts (used, e.g. for giving the green light of fireworks). The mineral is also used for the preparation of the finer quality of barium sulphate ('blanc-fixé') used for facing glazed papers. The addition of a small proportion of witherite to clay (1 oz. per cwt.) in brick making prevents any efflorescence and discoloration due to soluble sulphates. Although insoluble in water, it is poisonous, since it is readily acted upon by the gastric juice; and the powdered mineral, mixed with meal, is used as rat poison.

WITT'S RULE v. COLOUR AND CHEMICAL CONSTITUTION.

WOAD (*Voude*, Pastel, Fr.; *Waid*, Ger.). This commercial product is a dark clay-like preparation made from the leaves of the woad-plant, *Isatis tinctoria* (Linn.), an erect, herbaceous, biennial plant, belonging to the *Cruciferae*, bearing yellow flowers, small flat elliptical pods, and large smooth lanceolate or spatulate leaves.

The term 'woad' is derived from the Saxon 'wad,' which it has been suggested is derived from Woden, the Saxon God of War. It is synonymous with the Gallic *glastum*, with which, according to Pliny, the ancient Britons dyed their skin blue, in time of war and in connection with certain religious observances.

The plant is a native of Southern Europe, and from very early times has been employed in dyeing blue, for which purpose, previous to the introduction of indigo from India, it was largely cultivated in various parts of Europe—e.g. Thuringia, Languedoc, Piedmont, &c. Its cultivation has now declined almost to the vanishing-point.

In this country woad is now only grown, to a very small extent, in the fen lands of Lincolnshire and Huntingdon. The seed is sown in the early spring, March or April, and the young plants having been duly thinned and weeded, the leaves are ready for the first plucking in June, which, at intervals of five or six weeks, is repeated once or twice, or as often as fresh leaves shoot up.

The newly-gathered leaves are at once crushed or ground in edge-runner mills to a pulp, which is then placed in small heaps, to

drain, till sufficiently dry to cohere and be submitted to the 'bailing' process. This consists in working the pasty mass by hand into balls, 4-6 ins. in diameter. These are at once spread out on wicker-work trays or 'fleaks,' and thoroughly dried in well-ventilated sheds. The balls are stored in a dry airy place till the whole crop has been gathered, and are then submitted to the so-called 'couching'—i.e. a fermentation—process. For this purpose the balls are ground to a coarse powder, which is spread on the floor of the couching-house to a depth of 2 or 3 feet, and there reduced again to the consistency of a paste by frequent sprinkling with water and turning over with shovels. During this process, which lasts from twenty to forty days, the mass becomes heated and abundant offensive odours are given off. The operation needs to be conducted with some care and skill, so that the fermentation is neither so slow that a 'heavy' product is obtained, nor so rapid as to give one which is 'foxy.' When the fermentation has subsided, and the stiff, pasty mass is sufficiently cooled, it is packed in casks ready for the market.

It has been calculated that 9 parts by weight of woad leaves yield one part of the prepared product.

Although woad was formerly used for the indigo contained in it, it is at present only employed for the purpose of exciting fermentation in the indigo-vat ordinarily used by the woollen dyer, which is therefore termed the 'woad-vat.'

According to Wendelstadt and Binz (Ber. 1906, 39, 1627) woad contains two distinct micro-organisms, one of which under suitable conditions appears to be able to reduce indigo.

Spurious woad was sometimes prepared from the leaves of the rhubarb, cabbage, &c., but these products were very inferior to the true woad.

The colouring principle of woad leaves, considered by Schunck to be identical with that present in the *Indigofera*, is now known to be a distinct substance. This has not been isolated in a pure condition, but in its general reactions resembles indoxyllic acid (see INDIGO, NATURAL).

Other Literature.—Chevreul, J. Pharm. Chim. 1808, 66, 369; 1817, 350; Ann. Chim. 68, 284; Gilbert, Annalen, 41, 245; 42, 315; Trommsdorff, J. Pharm. Chim. 19, 93; Paris, Mus. Hist. Nat. Ann. 18, 251. A. G. P.

WÖHLERITE. Silicate, zirconate, columbate, and fluoride of calcium and sodium with the approximate formula $\text{Ca}_{11}\text{Na}_2\text{Si}_{11}\text{Zr}_2\text{Cb}_2\text{F}_2\text{O}_{12}$, and containing ZrO_2 15-23 p.c. The monoclinic crystals have the form of rectangular plates of a honey-yellow colour; sp.gr. 3.4; H. 6; decomposed by hot strong hydrochloric acid with separation of silica and columbic oxide. The mineral is usually regarded as a member of the pyroxene group. It occurs in nepheline-syenites in the Langesund-fjord in the south of Norway, in the Los Islands off the coast of French Guinea, and at Red Hill in New Hampshire; and in nepheline-phonolite in Haute-Loire, Auvergne. L. J. S.

WOLFRAM v. Tungsten.

WOLFRAMINE v. Tungstamine.

WOLFRAMITE or WOLFRAM. A mineral

consisting of iron and manganese tungstate (Fe,MnWO_4), crystallising in the monoclinic system. The name *ferberite* is applied to the members at the iron end of the series (FeWO_4), and *hübnerite* to those richest in manganese (MnWO_4). With this wide difference in composition the percentage of tungsten varies only slightly (WO_3 , 76.3-76.6 p.c.; analyses of the pure mineral show 74-77 p.c.). The mineral fuses readily before the blowpipe to a black, magnetic bead; and it is decomposed by *aqua regia*, with the separation of yellow tungstic oxide. Distinctly formed crystals are rare, but cleavage masses are of common occurrence. There is a perfect cleavage in one direction, parallel to the plane of symmetry. The mineral is opaque with a bright, sub-metallic lustre and a dark brown to black colour; the streak is dark reddish-brown to black; H. 5½. The high sp.gr. (7.2-7.5) and the lath-shaped cleavages are characters which assist in the identification of the mineral; while the latter character helps to distinguish it from other heavy black minerals. The name wolfram originated with the old German miners, and means, apparently, 'wolf froth,' since Agricola (1546) refers to the mineral as *lupi spuma*.

Wolframite usually occurs in veins traversing granitic rocks, and is often associated with tin ore. It is, in fact, obtained commercially mainly from tin mining districts; and formerly, before the mineral was of value, it was a source of trouble to the tin miner, since having about the same density as cassiterite it could not be separated from the ore by the ordinary mechanical methods. At one time it was eliminated in a soluble form by fusing the ore with soda (Oxland's process); but now it is extracted by the electromagnet (wolframite being weakly magnetic), and it forms a product as valuable as the tin ore itself. The principal wolfram-producing countries, arranged approximately in the order of their outputs, are: Lower Burma (at Tavoy), United States (Black Hills in South Dakota, Boulder and Gilpin counties in Colorado, Arizona, Nevada, &c.), Portugal, North Queensland (at Wolfram Camp, &c.), Bolivia, Peru, Argentina, Spain, England (Redruth, Bodmin Moor, and Gunnislake in Cornwall; Carrock Fell in Cumberland), France, Rhodesia, Siam, and New Zealand.

The mineral is used mainly for the manufacture of ferro-tungsten and the hard and tough tungsten-steel for tools and magnets of magnetos, and of some other alloys (e.g. 'partium,' an alloy of tungsten and aluminium). Metallic tungsten is used as the filament of the so-called 'osram' electric lamps; as contacts for magnetos in place of platinum; and as a catalyst in the synthesis of ammonia. Wolframite is also used for the preparation of sodium tungstate and other salts.

WOLLASTONITE. Calcium metasilicate CaSiO_3 , crystallised in the monoclinic system, and belonging to the pyroxene group (q.v.) of rock-forming minerals. It differs, however, from the other members of this group in the directions of its cleavages, which are here along two planes perpendicular to the plane of symmetry and inclined to one another at $84^\circ 37'$. The mineral is white and opaque, sometimes with a pearly or silky lustre; sp.gr. 2.88-2.92; H. 5; decomposed by hydrochloric acid with separation of silica. It is a mineral of metamorphic origin, occurring in siliceous limestones that have been baked by intruded masses of igneous rocks. Bladed crystals are found in the limestone blocks ejected by Vesuvius, and large crystals, up to 10 inches in length and partly or wholly altered to quartz and opal, at the Santa Fé mine, in Chiapas, Mexico. Here, as is often the case elsewhere, the mineral is associated with bodies of metalliferous ores (H. F. Collins, *Min. Mag.*, 1903, 13, 356). The name wollastonite is after William Hyde Wollaston (1766-1828).

When heated, wollastonite changes at 1190° into the β -modification called pseudo-wollastonite (m.p. 1540°), which has been long known in slags and devitrified glasses under the name hexagonal calcium metasilicate. The latter has not been observed in nature, and the presumption is that wollastonite has been formed in contact-metamorphic limestones at a temperature below 1190° (E. T. Allen and W. P. White, *Amer. J. Sci.* 1906, 21, 89; 1909, 27, 1; A. L. Day and R. B. Sosman, *ibid.* 1911, 31, 341). L. J. S.

WONGSKY, WONGSHY, WONGSCHY, HOANG TCHY. A Chinese yellow dyestuff. It consists of the fruit of the *Gardenia grandiflora*. According to Rochleder (J. 1858, 475), it contains *rubichloric acid* (see MADDER) and *crocin*, the glucoside of *Crocinin*, which is also present in saffron (*Crocus sativus* [Linn.]). Wongsy dyes aluminium and tin mordanted fabrics a yellow, whereas with iron mordant an olive colour is produced.

WOOD APPLE GUM v. GUMS.

WOODBURYTYPE v. PHOTOGRAPHY.

WOOD, DESTRUCTIVE DISTILLATION OF.¹

Wood completely freed from water has the following composition:—

Carbon, 50 p.c.
Hydrogen, 6 p.c.
Oxygen, 42.75 p.c.
Ash, 1.25 p.c.

¹ M. Klar, *Technologie der Holzverkohlung*, 1919 Second Edition. Julius Springer, Berlin.

The chemical nature of wood may be said to consist principally of cellulose, lignin, water, and of ash-forming materials.

The lignin in wood may be oxidised and removed by treatment with chlorine dioxide (Schmidt and Graumann, *J. Chem. Soc. Abstr.* 1921, [I.] 912; A. C. von Euler, *Cellulosechem.* 1923, 4, 109; *Chem. Soc. Abstr.* 1924, 126, [ii.] 129).

If wood is heated in a closed vessel with the air partly or entirely excluded and the vapours and gases are allowed to escape, the cellulose and lignin molecules are broken up by processes, the nature of which is little understood, but which are characterised by the formation of charcoal, which is left as a residue, and by the formation of gases and vapours, the latter of which, when condensed, is known as pyro-ligneous acid. P. Klason, Heidenstam and Norlin¹ concluded that the destructive distillation of wood may be represented by the following equation:—

Total amount of products, contained in the pyro-ligneous acid, in the tar, and in the wood gases.

They proved further that the destructive distillation of cellulose forms the most important products, viz. charcoal, acetic acid and tar; whilst lignin forms principally charcoal, acetic acid, wood alcohol and tar.

The destructive distillation of wood is occasionally carried out for the purpose of producing charcoal only, but at present it is more frequently the case that the by-products, acetic acid and the wood alcohol, are the most important substances yielded.

As regards the value of various kinds of wood for the process of destructive distillation, it has been shown that hard woods give the best yields of charcoal, acetic acid, and wood alcohol, whilst soft woods give smaller amounts of these products. Soft woods, however, show a larger yield than pine wood, which yields, besides the above-named products, a certain amount of turpentine, pine oils and pine tar oils. Local market conditions must decide in each case what is the most desirable wood for the purpose.

All wood for destructive distillation is split into cord-wood averaging 6 ins. in diameter and 4 ft. long. This initial preparation is usually carried out in the forest, but at manufactories recently erected in the United States large logs are brought to the saw mill where all the timber is utilised, and only those logs unfit for other purposes are used for cord wood. The cord wood is stacked in an exposed situation if possible, where it is allowed to dry and season for about 18 months, after which the moisture content will be found to be quite constant. The length of time required for this seasoning varies with the climate, and although it is thought that the moisture content of 20 p.c. is the most desirable, it is frequently found necessary to use wood containing 30 p.c. or more. A high percentage of moisture in the wood is undesirable owing to the fact that it delays the distilling process, decreases the

yields of acetic acid, wood alcohol and charcoal, whilst at the same time it increases the amount of noncondensable gases and also the amount of fuel used for the purpose of supplying heat for the distillation.

The process of destructive distillation is carried out in closed vessels built of brick or iron, and heated either by allowing the products of combustion to come directly in contact with the wood, excluding any excess of air; or by transmitting the heat through the walls of the vessel. In either case the distilling apparatus is connected with a condenser, the purpose of which is to condense the vapours formed during the reaction.

The apparatus for the destructive distillation of wood may be said to consist of three principal parts:—

1st. The container for the wood.

2nd. The arrangement for generating and supplying the heat to the container.

3rd. A condenser connected with the container by an intermediate vapour pipe.

After the wood has been placed in the distilling apparatus and the heating started, the water contained in the wood is first driven off; when this is accomplished the destructive distillation of the cellulose and lignin begins and will be indicated by the formation of non-condensable gases and by the appearance of the so-called pyro-ligneous acid, a brown liquor of characteristic odour, in which considerable tar is found. When the temperature reaches 270° an exothermic reaction sets in which supplies most of the heat necessary for the distillation process. The end of the process will be indicated by the cooling of the pipe which connects the distilling apparatus with the condenser.

In carrying out this distilling process on a commercial scale, the three phases of the distillation, namely: the expulsion of the water, the heating of the wood to the point at which the exothermic reaction sets in, and the completion of the process by means of the above-named reaction, will not necessarily take place consecutively, owing to the fact that the large-sized apparatus used will not allow the heat to be transmitted uniformly to all the wood in the vessel. Hence part of the wood situated near the heating surface may be in the third phase of the process, whilst that not so near the source of heat may be still in the first phase.

In general, yields of various products from air-dried hard wood in percentage by weight will be as follows:—

Charcoal, 25 to 27 p.c.

Crude pyro-ligneous acid, 45 to 50 p.c.

Gases, 25 to 28 p.c.

The composition of the charcoal will be variable, depending upon the process used and particularly upon the temperature at which the distillation has been finished. The following table gives the composition of charcoal produced by several processes:—

Process	P.c. C	P.c. H	P.c. O+N	P.c. ash	Temp- erature
Old 'Mellor' process	80.36	8.74	8.72	1.17	above 500°
Kiln process	84.18	8.28	11.72	5.72	450°
Retort process	81.15	8.24	12.44	8.19	350°

¹ *Ark. Acad. Min. u. Geol.*, 1908, Bd. 3, 2.

The *crude pyroligneous acid* will be found to be composed chiefly as follows:—

Water, 81 p.c.

Wood alcohol, 3 to 4 p.c.

Acetic acid, 6 to 8 p.c.

Dissolved and suspended tar, 7 p.c.

Other compounds contained, such as aldehydes, ketones, allyl alcohol, amines, phenols, and hydrocarbons are not of commercial importance and are of interest only in the refining of wood alcohol. The wood tar obtained from hard wood has little commercial value and is generally used as fuel. Small amounts, however, are used for the manufacture of creosote and wood tar pitch.

The *non-condensable gas* obtained by the destructive distillation of wood, amounting to 25–28 p.c. of the weight of the wood, varies in composition during the different phases of the process, and is composed on an average of carbon dioxide, 60 p.c.; carbon monoxide, 30 p.c.; hydrogen and hydrocarbons, 10 p.c. This gas is generally used for heating the retorts or boilers, and its heating value is equivalent to about 4–5 p.c. of the heating value of the wood decomposed in the process of distillation.

DESTRUCTIVE DISTILLATION OF PINE WOOD

The destructive distillation of pine wood containing rosin and turpentine, besides the cellulose and lignin, will produce products

different from those obtained from hard wood. The turpentine being volatile with water vapour is almost completely distilled over during the first phase of the distillation. In this phase, also, the rosin melting and flowing from the wood cells, covers the surface of the wood and the bottom of the distillation retort. During the second phase, this rosin will be decomposed, yielding such products as pinoline, rosin oils, and a residue of rosin coke. The pinoline will be mixed, more or less, with the turpentine originally contained in the wood, the rosin oils will combine with the tar formed in the usual course of wood distillation, and the rosin coke will be mixed with the charcoal. The mixture of turpentine and pinoline is known as *crude wood turpentine*. The presence of the rosin oils in the pine wood tar gives it a peculiar orange colour when painted on wood, which property makes it of considerable value. The amounts of acetic acid, wood alcohol and charcoal obtained from pine wood are considerably less than in the case of hard wood distillation.

An active demand for wood turpentine, for pine wood tar and pine wood tar oils, with good prices for these products and cheap prices for the wood, may cause, under certain circumstances, pine wood to be preferred to hard wood. But these conditions will not be frequent, and since the yields of acetic acid and wood alcohol and also of charcoal are considerably less, as the container can be filled with a larger weight

FIG. 1.

Brick wood-distilling apparatus for an 80-cord charge heated by burning a portion of the charge.

of hard wood than of pine wood (on account of the lower specific gravity of the latter), the efficiency of a distilling plant using hard wood is higher than one of the same size employing pine wood.

VARIOUS FORMS OF DISTILLING APPARATUS FOR CORD WOOD.

The number of forms of apparatus actually used for this purpose is large, and still larger is the number of designs which have been described in the literature or by patents taken out in different countries.

Only the most important types in practical use are given in what follows.

I. Distilling Apparatus made of Brick.

a. *Charring of the wood in brick kilns by fire gases which come directly in contact with the wood.*

1. *Fire gases generated inside the distilling apparatus by burning a part of the charge.*—To this type belongs the so-called 'American kiln,' seen in Fig. 1. This apparatus consists of a brick chamber, of about 15,000 cub. ft. capacity,

holding 80 cords of wood filled in by a top iron door *a*. There is a bottom iron door provided for discharging the charcoal. 4 ins. \times 4 ins. air inlet holes *d, d* are provided in the lower parts of the wall, and a couple of these kilns are connected by a brick goose neck *e* with the main smoke pipe, mostly built of wood. This main smoke pipe connects the kilns with the condenser plant *f g h*, and a fan is used for transporting the vapours and the gases from the kilns to the condensers and also for supplying the kilns with a certain amount of air, sufficient to generate the heat required for the destructive distillation of the wood by burning a certain amount of the wood, but avoiding any excess of air.

In the large plants at work in Michigan, often as many as 80 kilns are connected with condensers, using as much as 250 cords of wood per day, and condensing up to 50,000 gallons of crude pyroligneous acid. Unfortunately these kilns do not afford the proper amount of volatile by-products (acetic acid and wood alcohol) and about 50 p.c. of the possible yield is lost by being burnt to carbon dioxide and water. These kilns should only be used when wood is very

cheap and fuel and labour prices high and when there is not much demand for calcium acetate and wood alcohol. As these conditions seldom coexist, the kiln system must be considered wasteful and should be no longer used.

2. Fire gases are generated outside of the distilling apparatus by fuel (mostly wood) in a special fireplace and conducted from there to the wood — Fig. 2 represents such a type, originally known

FIG 2

Brick wood-distilling apparatus according to Schwartz heated by a special open fire

as the 'Schwartz kiln'. The Swedish kilns of Ljungberg and of Ottelinska are of a similar type.

b. Heating the wood in brick kilns by fire gas which, passed through radiators, transmits the heat by radiation to the wood

Inside a brick chamber, cast iron or steel radiators are provided, through which fire gases are passed, which transmit the heat by radiation to the wood surrounding these radiators

The oldest type of this kind of a wood distilling apparatus is represented by the 'Reichenbach kiln.'

Sweden developed a new form of this type called the 'Tube Oven,' seen in Fig 3

These brick kilns do not permit the charcoal to be discharged immediately after the distillation is finished. In fact, every hole of the oven

FIG. 3

Brick wood-distilling apparatus heated by steel coil radiators

has to be closed by bricks so as to allow the charcoal to cool with absolute exclusion of air. This cooling process requires, in the case of large sized kilns (50 cords or more), as much as eight days, and the efficiency is decreased correspondingly. In order to discharge the charcoal from kilns heated by radiators, immediately after the close of the distillation, the wood must

be loaded on iron cars capable of being pulled or pushed into the brick container. After the distillation is finished the cars, loaded with hot charcoal, are pulled out quickly and transferred to a steel chamber of the shape of the brick container, when cooling will not require more than 24 to 48 hours. After the cars are withdrawn, other cars, already loaded with new wood and ready for charging, will be put into the brick chamber, still hot by the previous operation

These brick kilns, heated by radiators, charged and discharged by iron cars, are the newest form of brick distilling apparatus.

A distilling apparatus built of brick is cheaper to build and possibly cheaper to maintain, but gives lower yields than steel apparatus as regards acetic acid and wood alcohol

FIG. 4

Vertical steel wood distilling apparatus for large charges, heated by fire gases circulating around the steel container, called 'Carboven', used in Sweden

on account of the difficulty of preventing the brick walls from leaking

II. Steel Distilling Apparatus.

A Intermittently operated apparatus.

The most important representative of this type is the Swedish 'Carboven,' shown in Fig. 4. This apparatus can be loaded with 100 cords of wood, and will require about three weeks for filling, distilling, cooling and discharging.

A couple of inner vertical heating tubes, instead of one large one, is the characteristic feature of the modern steel distilling apparatus,

B Apparatus for discharging the charcoal immediately after the close of the distillation without cooling the charcoal before discharging.

1. Horizontal types — a. Apparatus for small charges. — To these belong the distilling apparatus, generally called 'retorts,' largely used in the past and still employed in Germany, Austria, Russia, Pennsylvania, and other countries or states. These retorts are about 30 ins. in diameter by 10 ft. in length, are round in section, and contain $\frac{1}{2}$ cord wood. But they are also built for one cord capacity. Usually, and now

of these retorts is heated by the same fireplace, the products of combustion being conducted around the horizontally placed steel cylinders. One side of the retort is provided with a cast-iron door, the other tight end with a nozzle which serves to connect the retort with a condenser (see Fig. 5).

The wood is loaded by hand into these retorts. Inside the retort there is a semi-circular scraper, which is pushed to the rear before the retort is loaded and is provided with a rod with a handle ending near the door. After

the distillation is finished, a steel container is placed underneath the front of the door. The door is opened, and by means of the scraper the hot and burning charcoal is quickly emptied into the steel container, the cover of which is then closed air tight. A new charge is loaded immediately after discharging. While the new charge is distilling, the charcoal cools inside the container, which is built of thin sheet steel.

As one of these 39 ins. \times 10 ft. retorts can handle only $\frac{1}{2}$ cord of wood in 24 hours, this type of distilling apparatus is not well adapted for

FIG. 5.

Horizontal steel retort for small charges; type, F. H. Meyer, Hanover-Hainholz.

the destructive distillation of wood on a large scale.

These small, horizontal retorts have the further disadvantage that the scraper used in discharging them causes much of the charcoal to be broken into small pieces. The charging of the retort by hand also requires many workmen, causing loss of time and decreasing the efficiency of the plant.

β . Wood distilling apparatus for large charges arranged for mechanically charging and discharging—The disadvantages above mentioned may

be avoided by employing retorts of large capacity, provided with mechanical contrivances for filling them with wood and also for discharging the charcoal. The distilling apparatus which meets these conditions best is the so called 'car retort.' A distilling apparatus of this kind consists of a horizontal steel retort, capable of working off a charge of 6 to 10 cords of wood (see Fig. 6). The wood is loaded on cars which are pulled or pushed into the retort; this has rails on the bottom and, according to its capacity, one or two doors for filling and

FIG. 6.

Horizontal steel retort, filled and discharged by cars; for charges up to 10 cords; type, F. H. Meyer, Hanover-Hainholz.

discharging. Each car, made of steel, contains usually two cords of wood. The retort is connected by necks with one or two condensers of the usual tube type. The heating of these retorts is mainly effected by an open wood or coal fire and, to some extent, also by burning the tar and the gases obtained in the destructive distillation of the wood. The combustion gases travel by flues round the retort and escape in a smoke stack. The heating by an open fire has lately been replaced by producer-gas, obtained either in the usual way, that is generated by gas producers, or as a by-product in

the destructive distillation of the wood. A gas-heated retort will last longer, will use less fuel, and will yield higher results. The question of the best kind of gas producer for this purpose is dealt with later. After the distillation is finished the doors of the retort are opened and the cars, containing the hot charcoal, withdrawn and transferred as soon as possible to a horizontal steel cylinder, exactly corresponding in shape with the retort and also provided with doors for filling and discharging. The withdrawal of the cars is mostly done by means of a locomotive or by means of transportable electric

or steam hoists, and has to be done quickly in order to avoid the combustion of the charcoal. After the cars containing the hot charcoal are transferred to the horizontal steel cylinder, placed opposite the retort, the doors of the cylinder are closed air tight and the charcoal allowed to cool with exclusion of air. The cooling requires, according to the weather and character of the wood, from 24 to 40 hours.

This kind of wood-distilling apparatus further allows of the preliminary heating of the wood before filling it into the retort, by means of the waste combustion gases, which escape from the last retort flue into the smoke stack. In order to utilise this waste heat, the cars loaded with the wood are placed in a brick channel located opposite the charging door of the retort. The waste combustion gases are driven over the wood by means of a fan.

FIG. 7.

Vertical portable retort; type, F. H. Meyer, Hanover-Hainholz.

Fig. 6 shows a modern distilling apparatus, having a higher efficiency than any other wood-distilling apparatus in practical operation.

A charge of 10 cords of wood is worked off in 24 hours, including filling, distilling and discharging, and it requires also very few workmen to attend to the firing, charging and discharging. By discharging the charcoal in a cold state and without the use of scrapers, a better class charcoal is obtained with the production of only a very small amount of powder or small pieces.

A revolving retort of a capacity corresponding to a charge of 6 to 10 cords of wood has been tried but discarded on account of the difficulty of contriving proper outlets and of keeping these outlets tight. Moreover, revolving retorts gave, of course, large amounts of charcoal powder and small charcoal.

2. Vertical steel retorts.—Vertical steel retorts, either built stationary or transportable, are in use in Germany, Belgium, France, Italy,

and also in Russia. France, in particular, is the country of vertical retorts, which are almost always constructed as transportable ones. These retorts contain a charge of 1 to 1½ cords of wood and are heated by an open fire or by a gas fire from underneath (see Fig. 7). They are filled outside of the settings, after being placed in a horizontal position. After the retort is loaded and closed it is lifted, by means of a travelling crane, above the open space in the settings to which the retort belongs. Then the retort is lowered into its place and its cover connected, by means of a copper goose-neck, with the condenser. After the distillation is finished, this copper goose-neck is taken off, the goose-neck hole in the cover closed, and then the whole retort is lifted out of the settings by means of the crane and transported outside of the building, placed in a horizontal position and then allowed to cool down, which will require from 12 to 24 hours, according to the charge and the weather. These retorts give good yields and afford good charcoal, but their efficiency is not so good as that of the car retorts already described.

Sometimes these vertical retorts are constructed stationary and provided with a charcoal discharging door on the bottom. They are not as convenient as the transportable ones and do not give the same quality of charcoal, because the discharging is done by dumping, which causes breakages of the charcoal.

C. Continuously-working wood-distilling apparatus.

The distilling apparatus above described is either operated intermittently or only partly continuously.

But there are some types of distilling apparatus which are designed for continuous working as, for instance, the Swedish Groendal retort, which belongs to the type of the car retorts described on p. 493.

The Groendal retort consists of three main parts, namely:

1st. The drying chamber, built either of brick or of steel.

2nd. The distilling apparatus consisting of a horizontal steel retort.

3rd. The cooling apparatus for the charcoal, consisting of a steel cylinder of the shape of the retort.

These three parts are connected together but can be separated one from the other by means of vertical sliding doors of iron. The wood, loaded on cars, is filled in the drying chamber through which the exhaust combustion gases, escaping from the retort flues, are passed. After the drying is complete, the sliding doors between this drying chamber and the retort are lifted and the load transferred into the distilling zone of the system. This distilling apparatus is heated by any kind of heat generated by open fire or gas producers. The combustion gases travel around the steel shells, thus transmitting the heat to the wood inside the shell.

After the wood cars have passed the distilling part of the system, another slide door is opened and the cars with the finished charcoal are transferred into the charcoal cooling chamber, through which the cold non-condensable gases,

escaping from the condensers of the wood-distilling apparatus, are passed in order to do the cooling work and preheat the gases. A double sliding door at the other end of the system allows the cooled cars with the cooled charcoal to be continuously passed out.

Another continuously working wood-distilling apparatus which may be mentioned here is the wood-gas producer, which, however, does not yield any charcoal. This wood-gas producer is used for the generating of heating gas from second-class cord wood or wood refuse in order to heat boilers and retorts, but also to recover, at the same time, the by-products of the destructive distillation of wood, viz. acetic acid and wood alcohol. These gas producers (Fig. 8) consist of a vertical brick or brick-lined steel furnace provided on the top with a funnel with double doors for filling the gas producer with wood while in work. The bottom of this

Fig. 8.

Wood-gas producers; type, F H Meyer, Hanover-Hainholz.

gas producer is provided with an iron grate through which a certain amount of air is allowed to enter. The upper part is connected with a condenser. In order to start the gas producers, charcoal has to be put upon the grate and allowed to become red hot. Then the filling in of the wood is started by means of the double-door funnel above-mentioned. The condenser, connected with this gas producer, communicates by means of a gas flue with the smoke stack of the boilers or the retorts, and by the natural draught of this smoke stack a certain amount of air enters through the grate into the gas producer, generating producer gas when coming in contact with the hot charcoal. This hot producer gas carbonises the wood on the top of the charcoal zone on its way up to the outlet, and forms, at the same time, the products of the destructive distillation. These escape, together with the producer gas obtained by passing air through the hot charcoal layer, into the condenser, and while the non-condensable gases escape by the main gas flue, the vapours of pyroligneous acid and of tar are condensed and discharged by means of a siphon. In such a gas producer, there will be a hot charcoal zone on

the bottom, above this there will be wood in the distilling state, and above this zone there will be another zone of wood in the drying period, and on the top of this drying zone there will be the zone of the green wood, filled through the funnel.

These gas producers are not very efficient; they yield no charcoal and only 50 p.c. of the amount of acetic acid and wood alcohol obtainable from the same amount of wood when distilled in retorts. But considering that they produce heating gas and at the same time allow 50 p.c. of the acetic acid and the wood alcohol to be recovered, they are important and economical in working under favourable conditions.

Apparatus for the destructive distillation of pine wood, rich in turpentine and rosin.—As already mentioned, some varieties of pine wood contain, besides cellulose and lignin, large quantities of rosin and turpentine.

As it is the purpose of the pine wood distillation to separate the turpentine in its original state as much as possible before the destructive distillation of the cellulose, lignin and rosin sets in, the apparatus for the destructive distillation of pine wood of this kind must be provided by a heating system which allows a uniform transmission of heat to any and every part of the wood contained in the retort, or which at least allows the temperature to be under control.

It has been proposed to heat the retorts for this purpose by electricity instead of by an open fire or by superheated air or gases circulating around the retort; by oil or metal bath contained in a double jacket; or by superheated steam brought directly in contact with the wood.

These proposals are still in the experimental stage, but it would seem that these methods of heating are too expensive, inasmuch as a carefully designed gas-heating system, using gas, producer gas, or natural gas, will do the same work more economically.

Any one of the apparatus already described may in general be employed for pine wood distillation. But for recovering the turpentine in its original state, or at least not very much contaminated with the products of the destructive distillation of the wood and rosin, the smaller units (6 cords capacity) of ear retorts, heated by means of uniformly distributed gas burners, are most to be recommended.

DESTRUCTIVE DISTILLATION OF WASTE WOOD OR SPENT WOOD.

The splitting of the logs and cutting these into cord wood furnishes a large amount of small-sized wood waste. Also cutting the log into timber and working up the timber furnishes another class of waste wood known as slabs, edgings, shavings, sawdust, and so on.

As long as this wood waste consists of pieces large enough to furnish charcoal of the usual size, it can be handled just as cord wood in the standard retorts, and it will yield almost the same amount of charcoal, wood alcohol and calcium acetate as cord wood obtained from the same log, when these figures are referred to the weight and not to the volume of the wood, as a cord of slabs or edgings will weigh very much less than a cord of real cord wood.

With regard to the destructive distillation of

sawdust or shavings, this raw material is not capable of being distilled in any one of the standard apparatus previously described, on account of its voluminous character or by reason of the fact that there is not enough air space between the small, single wood pieces whereby the escape of the vapours and gases, formed on distillation, is rendered impossible. Back

pressure, and under unfavourable circumstances even an explosion, will be the consequence of trying to distill sawdust or other wood of this form in the standard wood distilling apparatus.

There have been numerous proposals to distill sawdust or other fine wood, and almost every one of these proposals is based either on the use of thin layers of sawdust or the use of stirring

FIG. 9.

Retort for distilling small wood waste

contrivances, or of a combined system of thin sawdust layers and stirring contrivances or scrapers, or finally on the briquetting of the sawdust before it is distilled.

None of these apparatus has taken a practical form, at least on a large scale up to the

price, for the large quantities of charcoal powder produced.

Figs 9 and 10 show types of apparatus which are used for this purpose. The apparatus (Fig. 9) transfers the sawdust continuously by means of scrapers over fire heated steel plates, while in the apparatus in Fig. 10 the sawdust continuously drops down in thin layers by its own gravity between the space of the fire-heated shell of the vertical retort and the cast iron rings, which serve as outlets for the vapours and gases.

FIG. 10.

Vertical retort for the continuous distillation of small wood waste, type, F. H. Meyer

present time, neither small nor large plants which handle sawdust or a similar class of wood, are operated economically on account of the large initial outlay, which is out of proportion to the value of the output and on account of the fact that there is no market, at a sufficient

TREATING THE CRUDE PYROLIGNEOUS ACID.

Crude pyroligneous acid consists of a watery solution containing acetic acid, wood alcohol and its companions (aldehydes, ethers, ketones, allyl alcohol, phenols) and tarry matters in solution. This brown liquid is further mixed with tar in suspension.

Crude pyroligneous acid cannot be sold in large quantities, but acetate of lime and crude wood alcohol are in large demand.

The object of treating the crude pyroligneous acid is to separate the acetic acid and the wood alcohol from the water and the tarry materials.

First the tar, suspended in the liquid, is separated by allowing the liquor to stand. The tar will settle either on the top or on the bottom of the pyroligneous acid and is then drawn off.

But the remaining liquid still holds tar in solution and this dissolved tar must be separated in order to make marketable acetate of lime, which must contain at least 80 to 85 p.c. $(CH_3COO)_2Ca$.

There are several methods employed in order to separate the tarry matters in solution or suspension from the crude pyroligneous acid. The oldest process, still in use in some plants, consists in a simple redistillation of the crude pyroligneous acid in copper stills, connected

with a condenser and heated either by an open fire or better by a steam coil (Fig. 11). The tar remains as a residue. The distillate is a more or less water-white liquid, which is now practically free from tar and contains principally water, acetic acid, wood alcohol and its associated products above mentioned.

This method of removing the dissolved tar by simple distillation requires about 50 p.c. of

Fig. 11.

Apparatus for distilling crude pyroligneous acid; type, F. H. Meyer.

the total amount of fuel or steam generated in a wood-distilling plant.

The author of this article introduced new methods of distillation of the crude pyroligneous acid, and up to date the crude pyroligneous acid of about 1000 cords of wood is so treated.

This process is based on the principle of the multiple effect evaporators, originally used in the manufacture of sugar (Fig. 12). Two or

Fig. 12.

Apparatus for continuous distillation of crude pyroligneous acid in multiple effect stills; type, F. H. Meyer.

more distilling stills are used, one connected with the other and provided with contrivances to maintain a different but gradually lowered boiling-point or a different but gradually lowered working pressure in each one of the stills. For instance, still 1 will be heated by steam of 15 lbs. pressure, using a steam coil or any other heating contrivance.

The liquor, surrounding this steam-heated contrivance, is kept under atmospheric pressure. The pyroligneous acid vapours, generated in still 1 by means of the heating effect of the steam, enter the heating contrivance of the second still, kept under a lower pressure by means of vacuum and therefore a lower

boiling-point of the liquid than in still 1. Therefore the pyroligneous acid vapours, escaping from the first still, heat and distil the crude pyroligneous acid in the second still. This system can be continued indefinitely theoretically, but a system of four combined stills is all that can be reached practically.

A distilling apparatus of this type requires only one-third of the amount of steam or fuel hitherto used for distilling the crude pyroligneous acid in simple distilling apparatus; or the saving may amount to 100 p.c. when sufficient exhaust steam is available. Fig. 12 shows such an installation, based on the multiple effect distilling system.

Besides these two processes, used for redistilling the crude pyroligneous acid, there is another, employed more particularly in German plants.

This process combines the distillation of the crude pyroligneous acid with the neutralisation of the tar-free distillate by means of milk of lime or soda ash and the separation of the wood alcohol from the acetate solution.

The pyroligneous acid is distilled in a copper still, heated by a steam coil. Instead of passing the vapours of pyroligneous acid into a condenser, they are forced through milk of lime or soda ash solution, contained in closed copper or iron tanks, which are connected with a condenser (Fig. 13). The acetic acid thus combines with the lime or the soda, forming acetate solutions, whilst the wood alcohol and water vapours escape to the condenser from which an aqueous solution of the alcohol is discharged containing 5 to 12 p.c. wood spirit.

All the processes described above for removing tarry matters before treating the pyroligneous acid with milk of lime or soda ash solution, are based on the *distillation principle* and handle the gross distillate discharged from the condensers connected with the wood distilling apparatus.

The writer has introduced another patented process which is not based on the redistillation of crude pyroligneous acid, but depends on separating the total amount of tarry matters from the vapours escaping from the wood-distilling apparatus *before* these vapours are condensed. This is effected by washing the vapours and gases by means of crude wood tar or a mixture of crude wood tar and pyroligneous acid in two or more gas washing apparatus, which are combined together, and maintaining in each one a gradually decreasing temperature.

For instance, in the tar washer 1, a temperature of about 300°F. may be maintained and in the last tar washer, or the washer next the condenser, a temperature of 212°F. may be maintained.

By the combined effect of the fractional condensation of the tar and of the absorbing affinity of the large amounts of tar used as a washing liquid, for the small amounts of tar contained in the form of vapours in the products, the pyroligneous acid discharged from the condenser will be practically free from tar and ready to be neutralised by milk of lime or soda ash.

This process is successfully used in many wood-distilling plants and saves entirely the expense of the redistillation of the crude product.

MANUFACTURE OF ACETATE OF LIME FROM CRUDE PYROLIGNEOUS ACID.

As already mentioned, grey acetate of lime, 80 to 82 p.c., is the product into which the acetic acid, contained in the pyroligneous acid, has to be transformed for the purposes of shipment.

The manufacture of grey acetate of lime starts with the tar-free distillate, obtained from the crude tar containing pyroligneous acid by one of the processes already described. This distillate is neutralised either by mixing it with milk of lime in a wooden tank, provided with a stirrer and cover, or by passing the vapours through layers of milk of lime.

The milk of lime combines with the acetic acid; it partly saponifies any methyl acetate; it transforms some of the aldehydes into insoluble resins; and it combines with phenols, forming insoluble lime compounds. After adding the milk of lime, the neutralised liquor is allowed to stand in order that the precipitates, formed by the neutralising processes, shall settle.

The next operation on the settled liquid, containing principally wood alcohol and its associates, acetate of lime and water, consists in separating the wood alcohol from the aqueous solution of the acetate of lime, either in form of a weak alcohol solution by means of a simple intermittently operated still, or in form of

FIG. 13.

Apparatus for distilling crude pyroligneous acid by passing acid vapours through layers of milk of lime; type, F. H. Meyer.

concentrated wood alcohol by means of an intermittently or continuously operated rectifier.

The simple distilling still furnishes a weak wood alcohol solution, containing from 8 to 10 p.c. of wood alcohol, whilst the rectifier turns out by a single operation crude wood alcohol from 30 to 95 p.c., depending upon the design of the rectifier.

The simple still consists of a steel or copper still, provided with a copper heating coil and connected with a condenser.

The intermittently operated rectifier, shown in Fig. 14, is built of a steel or copper still with a copper heating coil, a copper column with rectifying sieve or bell plates, a separator and condenser. The working principle of these rectifiers is based on fractional distillation, and the 'columns' used for this purpose are very similar to those employed in manufacturing grain alcohol and known as the 'Savalle apparatus' from the name of the inventor. The

continuously working rectifiers, for separating the crude wood alcohol in a concentrated state from the neutralised liquor, are the most modern and most economically working apparatus for this purpose (Fig. 15). They have been introduced in the wood-distilling industry by the author of this article, and they furnish by a single operation the so-called 'crude wood alcohol' of 95 p.c. and separate at the same time the oils, originally contained in the neutralised liquor and also the acetone, if desired.

The continuously working apparatus are principally built of two columns; at the top of one column the neutralised liquor enters and the second column takes the wood-alcohol vapours escaping from the first column. The neutralised liquor travels in the first column downwards from plate to plate and meets on its way down the steam, entering into the bottom section. The wood alcohol, containing about 30 p.c. of wood alcohol and 70 p.c. of water,

escapes from the top section of the first column, while the acetate of lime solution freed from wood alcohol, is continuously discharged from the bottom section of this column. The 30 p.c. wood alcohol vapours enter the bottom part of second column, and on their way upwards from plate to plate they are concentrated by means of fractional distillation and discharged from

FIG. 14.

the top section to a separator and from there to a final condenser, leaving the latter as a product containing up to 95 p.c. wood alcohol.

This product corresponds in chemical composition and physical characters with the so-called 'American Crude Wood Alcohol,' shipped in immense quantities from the United States to Europe. It still contains the total amount of acetone, aldehydes, ketones, esters, ammonia, amines, and allyl alcohol, originally contained in the neutralised liquor, and also some of the 'wood oils,' which always accompany the wood alcohol.

The average composition of this product may be given as follows:—

16 p.c. acetone and other ketones.

8 p.c. aldehydes, methyl acetate, amines, allyl alcohol and oils.

70 p. c. methyl alcohol.

8 p.c. water.

The following substances have also been found in 'wood spirit oil,' the residue left after the isolation of methyl alcohol from wood spirit: methyl ethyl ketone, methyl isopropyl ketone, dipropionyl-ethane, mesityl oxide, trimethyl acetic aldehyde, isovaleric aldehyde, Δ^4 -hexene-3-one, cyclopentanone (Pringsheim and Leibowitz, Ber. 1923, 56, [a] 2034; Chem. Soc. Abstr. 1923, 194, 1, 1052).

In order to manufacture 'pure' methyl alcohol from the crude wood alcohol, all these contaminating products have to be separated.

This is done by fractional distillation, carried out systematically by means of intermittently or continuously operated rectifiers, similar to those above described. The separation is usually assisted by adding chemicals—for instance, caustic soda and sulphuric acid—which destroy, polymerise, or saponify the products to be separated—for instance, aldehydes, esters, ketones, phenols, amines, and so on.

The separation of the acetone and the allyl alcohol, which are always associated with the methyl alcohol, is *entirely done* by a carefully repeated fractional distillation, which yields the concentrated acetone in form of 'head ends' and the allyl alcohol in form of 'tail ends.'

A mixture containing in specified proportion these head ends and tail ends represents the 'denaturing wood alcohol,' used practically everywhere for denaturing alcohol. This material must conform to certain specifications and tests prescribed by the different Governments.

The final product of such a repeated fractional

FIG. 15.

distillation, carried out either by intermittently working or continuously working rectifiers, represents the 'pure' methyl alcohol, which is free from acetone or contains only traces of it, and contains up to 99 p.c. real CH_3OH .

Besides this final product, free from acetone, and the 'denaturing wood alcohol' containing acetone, allyl alcohol, and other impurities, a

number of other wood alcohol grades are on the market; for instance, 'pure' methyl alcohol of 99½ p.c. with 0.1 to 1 p.c. of acetone and many other grades demanded by customers.

The pure grades are used for the manufacturing of aniline colours, of formaldehyde, of perfumes; the other grades for varnishes, as solvents, and the poorest grades for denaturing or burning.

The distillation of the neutralised liquor yields, as above shown, two products:

Wood alcohol, as a volatile product;

Acetate of lime solution as a non-volatile residue.

Fig. 16.

Open pan for evaporating acetate of lime solution.

This latter solution holds in suspension insoluble polymerised products, formed by a reaction between phenols and aldehydes with acetate of lime or traces of lime in excess, which must be settled by allowing the liquor to stand.

The settled solution contains varying quantities of acetate of lime, according to the nature of the original liquor and to the process used for distilling off the crude wood alcohol.

These quantities differ from 7 to 25 p.c.; this means, 100 lbs. acetate of lime solution may contain from 7 to 25 lbs. dry acetate of lime, 80-82 p.c. As it is impossible to recover the acetate of lime by a crystallising process on account of its equal solubility in cold and hot water, the solution must be boiled down until the salt is left in the solid state.

Up to the present this boiling was done in two steps. By the first step, the acetate of lime solution is evaporated in open, steam-heated, double-jacket pans (Fig. 16) just to the point at which the concentrated solution becomes solidified by crystallising. This point is reached when the acetate of lime solution contains about 35 to 40 p.c. of the dry salt. The crystallised magma is then spread out in thin layers upon an open drying floor, built of cast-iron plates or steel plates, heated by an open fire or by waste fire gases.

The operation of boiling down the acetate of lime solution to a magma of crystal requires very large amounts of steam on account of the coating of the heating surface by crystals and scales and by the immense reduction of the heat transmitting capacity.

Furthermore, the drying upon an open drying floor necessitates much hand work, as the material must be turned over and

gradually transferred from one end of the drying floor to the opposite one, whereby it travels with the current of the fire gases. This ensures that the wet acetate of lime, which can stand a high temperature, comes in contact with the hot fire gases, while the dried salt or partly dried salt comes only in contact with the fire gases of a lower temperature, in order to protect it against decomposition into acetone.

The author has introduced a drying process, in which the solution of acetate of lime will be continuously and mechanically evaporated and dried, doing away entirely with the steam-heated open pans and the high wages required by opening drying floors.

By this new process, already in successful operation in plants of all sizes from 30 cords up to 250 cords, the acetate of lime solution is continuously evaporated in specially designed multiple effect evaporating apparatus, operated on the same principle as above described for the multiple green liquor distillers.

The weak solution enters the first evaporator, travels from there to the second, and from the second to the third, leaving the same or the last one as a concentrated liquor, which contains up to 30 to 35 p.c. dry salt. This liquor will not crystallise when kept hot.

The liquor flows to a pan into which a rotary drum is dipping, heated inside by steam. This drum becomes coated with a thin layer of the concentrated solution.

While rotating, the thin layer dries quickly, and before the drum dips again into the concentrated solution the magma of crystals, which now coat the surface of the drum, is scraped off by means of knives, working on the surface of the drum (Fig. 17).

Fig. 17.

Continuous-working rotary evaporator for evaporating and drying acetate of lime; type, F. H. Meyer.

The magma of crystals then travels by means of a conveyor to a belt dryer, built of endless canvas belts or wire cloth belts, upon which the wet salt is transferred against a current of hot air or over pipe coils, heated by exhaust steam. This new type of apparatus for evaporating and drying acetate of lime does away with any kind of hand work; it obviates the disagreeable and unhealthy work of drying upon an open floor; and it saves almost all the wages hitherto spent for drying, and it saves, too, large amounts of fuel. Moreover, the acetate of lime obtained by this process, is of an even

form like peas; it does not contain much dust; it is of a brighter colour and is soft and voluminous, yielding on this account more acetic acid and acetone, when worked up into these products.

MANUFACTURE OF ACETATE OF SODA.

Next to acetate of lime, acetate of soda is the most important salt of acetic acid manufactured in wood-distilling factories.

In order to produce sodium acetate in a crystallised state, the distillate of pyroigneous acid, obtained by one of the processes already described, is neutralised by soda ash. The acetate of soda solution is then freed from wood alcohol by the methods before mentioned, and boiled down by open double-jacket pans, or by

modern multiple effect evaporating apparatus, until the crystallising point is reached. By the next step the condensed solution is completely dried in cast-iron, fire-heated pans, provided with scrapers, and the heating is continued until the whole of the water is driven off and the anhydrous sodium acetate is completely melted, when the liquid mass will have a temperature of about 320° . At this temperature, sodium acetate is not decomposed, but sodium propionate and butyrate, as well as tarry or resinous matters present in the original product, will be destroyed and converted into insoluble matters.

After melting, the mass is dissolved in water to form a concentrated solution and the charred matter separated by filtering the solution,

FIG. 18.

usually by a filter press. The filtrate is transferred to crystallising vessels and the crystals and mother liquor separated by a centrifugal machine. The crystals are recrystallised and the mother lees returned to the evaporating pans.

TREATING OF THE PRIMARY MARKETABLE PRODUCTS RESULTING FROM THE DESTRUCTIVE DISTILLATION OF WOOD.

The first products resulting from the destructive distillation of wood are: charcoal, crude pyroigneous acid, tar, when hard wood is distilled; or charcoal, crude pyroigneous acid, crude turpentine, crude pine oil and crude pine tar, when pine wood, containing turpentine and rosin, is employed. Of these, the charcoal only is ready for sale. The other products must be further treated in order to convert them into marketable commodities.

From the crude pyroigneous acid acetate of lime, acetate of soda and crude wood alcohol

are obtained, and from the latter the 'pure' methyl alcohol, the refined wood alcohol, and the denaturing alcohol as above described.

Many of the wood distilling factories work up the acetate of lime into acetic acid or acetone and the methyl alcohol into formaldehyde.

Manufacture of acetic acid.—In order to manufacture acetic acid, only acetate of lime, 80–82 p.c., is used nowadays as raw material. This is mixed with sulphuric acid of 92 to 98 p.c. in a closed cast-iron still, provided with stirrer and scrapers and heated by high-pressure steam (Fig. 18). After the mixing process is finished the acetic acid is distilled off, a vacuum being maintained in the still during the process of distilling. The crude acetic acid, resulting from the process, contains about 80 p.c. acetic acid (propionic and butyric acid included), traces of sulphur dioxide, and is of a yellow colour. This acid can be used for many purposes in the arts, as, for instance, manufacturing white lead, amyl acetate, &c.

In order to produce 'pure' glacial acetic acid of 96 to 99½ p.c., the crude 80 p.c. acetic acid, obtained by the action of sulphuric acid on acetate of lime, must be rectified in a copper rectifier (Fig. 19).

First a weak acetic acid is obtained containing propionic and butyric acid; then the distillate becomes gradually stronger and after distilling over 40 to 50 p.c. of the original charge, glacial acetic acid distills over: this has a melting-point of 14°-16° and contains 99 to 99½ p.c. CH_3COOH . At the end of the process the melting-point again falls, and with it the content of acetic acid owing to the presence of propionic and butyric acids.

In order to manufacture 'pure' acetic acid, 99½ p.c., corresponding to the requirements of the pharmacopoeas of different countries, the glacial acetic acid, obtained from the first rectification of the crude 80 p.c. acetic acid, will be oxidised and then redistilled by use of a simple still connected with a silver condenser.

Manufacture of acetone.—Acetone is manufactured by the dry or destructive distillation of

Fig. 19.

Apparatus for rectifying crude acetic acid in order to manufacture glacial acetic acid; type, F. H. Meyer.

calcium acetate. The process corresponds theoretically with the equation:

According to the author's patented process, used in most of the existing acetone factories, acetate of lime is spread out in thin layers on steel plates, to be placed one above the other upon platforms on steel cars, allowing sufficient

clearance from platform to platform (Fig. 20). These cars are pushed into horizontal steel retorts, heated by fire gases. The retorts are capable of treating from 3000 to 15,000 lbs. of

Fig. 20.

Retort for decomposing calcium acetate; type, F. H. Meyer.

calcium acetate in 24 hours and are connected with a condenser. The destructive distillation sets in at about 300°. After the charge is charred, the cars are withdrawn and other cars, already loaded, charged into the retort.

By the older acetone process, calcium acetate was distilled in charges not exceeding 1000 lbs. by means of fire-heated, closed, cast-iron pans, provided with a stirrer and scrapers. But these forms of apparatus yielded only 17 lbs. 'pure' acetone from 100 lbs. of calcium acetate instead of from 20 to 21 lbs. as obtained by the process above described.

There is a third process used, based on the distillation of calcium acetate by means of a stream of superheated steam which is brought directly in contact with the acetate.

The crude acetone obtained by one or other processes contains, besides the acetone, tarry matters, formic and acetic acids, aldehydes, ketones formed by the propionic acid and butyric acid originally contained in the crude material, hydrocarbons, and other products.

By means of repeated fractional distillation, assisted by the use of small amounts of caustic soda and sulphuric acid, acetone of 99½ p.c. is obtained, whilst the tarry matters remain in the residue. The acids are fixed by the alkalis, which destroy the aldehydes, and the foreign ketones and hydrocarbons are obtained as 'tail ends' from the rectifier, from the fact that their boiling-point is considerably higher than that of acetone.

FORMALDEHYDE.

This important disinfectant is obtained from the 'pure' methyl alcohol by oxidising it by the oxygen of the air under the influence of catalytic agents: $2\text{CH}_3\text{OH} + \text{O} = 2\text{CH}_2\text{O} + 2\text{H}_2\text{O}$. The manufacturing process differs in some respects from the theoretical equation, as side reactions set in whereby a part of this formaldehyde is broken up into carbon monoxide and hydrogen, according to the equation $\text{CH}_2\text{O} = \text{CO} + 2\text{H}$.

The excess of oxygen under the influence of the red hot catalytic material combines with the carbon monoxide as well as the hydrogen:
